## DEDICATION

My work on this 30th Edition of Gray's Anatomy  
is gratefully dedicated to my father and mother,  
ERMANN0 CLEMENTE AND CAROLINE CLEMENTE, who  
with great wisdom, taught me in my youth the  
everlasting value of education,  
and to

DR. WILLIAM FREDERICK WINDLE, my teacher,  
who taught me to understand a way of life so  
effectively stated in the following passage from  
Robert Frost:

. . . My object in living is to unite  
My avocation and my vocation,  
As my two eyes make one in sight.  
Only when love and need are one,  
And the work is play for mortal stakes,  
Is the deed ever truly done,  
For Heaven and the future's sakes.

# Henry Gray

F.R.S., F.R.C.S.

THE ORIGINATOR of this now famous book, which has reached its one hundred and twenty-fifth year of continuous publication in America, was born in Windsor, England, in 1825. A letter written to Lea & Febiger, by Henry Gray's great nephew, F. Lawrence Gray, has supplied this date as well as some interesting biographical information.

Henry's father, William Gray, was born in 1787. He is reported to have been an only child. Whether for protection or from special interest, he was placed in the royal household where he was brought up. In 1811, before the Regency, and while he was in his twenties, he was Deputy Treasurer to the Household of the Prince of Wales. On the accession of George IV as Regent in 1820, William Gray became the King's private messenger and continued in this capacity, with William IV, until his death at the age of forty-seven. He married Ann Walker in 1817 and during George IV's reign lived at Windsor Castle in accommodations provided for him and his wife. When William IV acceded to the throne in 1830, the Grays moved to London in order to be near Buckingham Palace, and either immediately or soon after that No. 8 Wilton Street became the family residence.

Henry Gray had two brothers and one sister. His younger brother, Robert, trained to become a naval surgeon. He died at sea in his twenty-second year. Henry's sister, younger than he, apparently never was married. His older brother, Thomas William, adopted the legal profession, and was Attor-

ney to the Queen's Bench in 1841, and, in 1846, Solicitor of the High Court of Chancery. He had a large family—seven sons and three daughters. His third son, Charles, the nephew whom Henry treated for smallpox in 1861, lived to the ripe age of fifty-three. His fifth son, Frederick, moved to South Africa, married in 1881 and had six children, one of whom was the F. Lawrence Gray mentioned above.

After his father's death in 1834, Henry Gray continued living at 8 Wilton Street with his mother, brothers and sister. This is undoubtedly the address from which he later carried on his short practice and the place where he wrote his famous book. He and his brothers were educated at one of the large London schools, possibly Westminster, Charterhouse, or St. Paul's. He was engaged to be married at the time of his death.

Henry Gray's signature appears on the pupil's book at St. George's Hospital, London, as a "perpetual student" entering on the 6th of May, 1845. Four years later, in 1849, his name appears in the Proceedings of the Royal Society with the M.R.C.S. after it, the approximate equivalent of our M.D. While still a student in 1848, he won the triennial prize of the Royal College of Surgeons for an essay entitled "The Origin, Connections and Distribution of the Nerves to the Human Eye and Its Appendages, Illustrated by Comparative Dissections of the Eye in Other Vertebrate Animals." He was appointed for the customary year as house surgeon to St. George's Hospital in 1850. Successively thereafter he held the posts of demonstrator of anatomy, curator of the museum, and lecturer on anatomy at St. George's Hospital. In 1861 he was surgeon to St. James Infirmary and was a candidate for the post of assistant surgeon to St. George's Hospital and would certainly have been elected had he not died from confluent smallpox which he contracted from his nephew, Charles, whom he was treating. He was buried at Highgate Cemetery in June 1861. Sir Benjamin Brodie, president of the Royal Society, wrote, "I am much grieved about poor Gray. His death, just as he was on the point of obtaining the reward of his labors, is a sad event indeed . . . Gray is a great loss to the hospital and school. Who is there to take his place?"

During his lifetime Henry Gray received outstanding recognition for his original investigations. That they have received so lit-

the mention since his death is as surprising as the lack of information about his life. The study of the eye which won him the Royal College of Surgeons prize was expanded into an embryological work, "On the development of the retina and optic nerve, and of the membranous labyrinth and auditory nerve," published in the *Philosophical Transactions of the Royal Society* in 1850. It contains the earliest description of the histogenesis of the retina. Two years later the *Transactions* contained another article, "On the development of the ductless glands in the chick." This must have stimulated Gray's interest in the spleen, which he classed as a ductless gland, because he obtained an allotment of funds for further study from the annual grant placed at the disposal of the Royal Society by Parliament for the promotion of science. The result was a monograph of 380 pages, "On the Structure and Use of the Spleen," which won him the triennial Astley Cooper Prize of £300 (about \$1,500.00) in 1853. It was published by J. W. Parker and Son in 1854, but appears now to be rare. Numerous "first observations" recorded in this book have escaped notice by all subsequent authors writing about the spleen. Gray described, among other things, the origin of the spleen from the dorsal mesogastrium ten years before Müller, who is usually given credit for the discovery.

As a result of his ability and accomplishment, Henry Gray was made a Fellow of the Royal Society at the very young age of twenty-five. Besides anatomy, his interests also included pathologic and clinical investigation. In 1853 he had a paper in the *Medico-Chirurgical Proceedings* entitled, "An Account of a Dissection of an Ovarian Cyst Which Contained Brain," and in 1856 a more extensive treatise entitled, "On Myeloid and Myelo-Cystic Tumours of Bone; Their Structure, Pathology, and Mode of Diagnosis."

His crowning achievement, however, and the one which is the source of his lasting fame is the publication, *Anatomy, Descriptive and Surgical*, now widely known as *Gray's Anatomy*.

## 125 Years of Gray's Anatomy

The first edition of *Gray's Anatomy* was published in London by J. W. Parker and Son in 1858 and in June of 1859 in Philadelphia

by Blanchard and Lea, who purchased the American rights for the book. The American edition was identical with the English, except that many typographic errors had been corrected, the index considerably improved, and the binding made more rugged. It contained xxxii + 754 pages and 363 figures. The drawings were the work of Dr. H. Van Dyke Carter, of whom Gray writes in his preface, "The Author gratefully acknowledges the great services he has derived, in the execution of this work, from the assistance of his friend, Dr. H. V. Carter, late Demonstrator of Anatomy at St. George's Hospital. All the drawings, from which the engravings were made, were executed by him. In the majority of cases, they have been copied from, or corrected by, recent dissections, made jointly by the Author and Dr. Carter."

Blanchard and Lea obtained the services of Dr. R. J. Dunglison to edit the first and the next four American editions. Dunglison corrected the typographic and other small errors and improved the index but made few alterations or additions in the text. Almost no adaptation was required because medical education in this country and in England were still much alike.

Henry Gray had just finished preparing the second edition before his untimely death. This was published in 1860 in England and in 1862 in this country under the editorship of Dunglison. The next edition published in America was a "New American from the 5th English Edition." This appeared in 1870 and was bound in either cloth or sheep. Another pause, and there appeared the "New American from the 8th English" in 1878, and "The New American from the 10th English" in 1883. Dunglison was again the editor, but a new editor, W. W. Keen, revised extensively the section of topographic anatomy at the end of the book. The following edition, a "New American from the Eleventh English," published in 1887, was edited and thoroughly revised by W. W. Keen. Color was used for the first time in the chapters on blood vessels and nerves. The "New American from the Thirteenth English" appeared in 1893, apparently edited by Keen and others.

In 1896 the reference to the English edition was dropped and we have the fourteenth edition with the editors Bern B. Gallaudet, F. J. Brockway, and J. P. McMurrich. J. C.

DaCosta, editor of the sixteenth edition in 1905, expanded the book, introducing much new material. E. A. Spitzka assisted DaCosta with the seventeenth edition in 1908 and edited the next two alone in 1910 and 1913. The publishers also tried a "New American from the Eighteenth English Edition" in 1913, but its sale was much smaller than that of the American edition of that year. In 1918, W. H. Lewis began his editorship, giving the book a scholarly treatment, reducing its length, improving the sections on embryology, and generally giving a more straightforward treatment of the various chapters. For his last edition, the twenty-fourth, published in 1942, he had the assistance of six associate editors.

Beginning with the twentieth edition in 1918, new editions appeared at regular intervals of six years; their dates and the names of the editors are listed on page vi. Dr. Charles Mayo Goss became responsible for the twenty-fifth through the twenty-ninth American Editions, these being spaced at five- to seven-year intervals. The twenty-

seventh Edition was published in 1959 in order to have its publication fall on the 100th year.

Since the beginning of this century, the American and English editions have tended to drift apart. Even from an early date, new American editions were less frequent than the English, and if the American editions had been numbered independently from the beginning, the present edition would be the twenty-fifth, whereas the current English edition is the thirty-sixth. Somewhat more of the imprint of Henry Gray has been preserved in this American edition, in the illustrations especially, as it still has nearly 200 drawings based on the original illustrations by Carter. This treatise, offered initially by a young English anatomist and surgeon, is the oldest continuously revised textbook still currently in use by the medical professions. After one hundred and twenty-five years, this enduring recognition is a tribute that, perhaps, even Henry Gray may not have conceived would happen.

## Preface

When I was asked to consider the preparation of this 30th American Edition of Gray's Anatomy, I spent an afternoon with Dr. Charles Mayo Goss at his home near Washington, D.C. Dr. Goss, who was affectionately known as "Chiz" by his many friends, had edited the five previous editions and had for the preceding three decades masterfully succeeded in retaining both the effectiveness and popularity of the book to students and practitioners of the medical, dental and other allied health professions. Dr. Goss warmly encouraged me to assume the responsibility for this 30th edition and recommended that I attempt to retain the classical tradition and style of the book, even if I planned, as he thought was necessary, a major revision of the text and figures. Chiz's twinkling smile should have alerted me to the enormous task that I was considering. Sadly, Dr. Goss's death in 1981 came about two years after I commenced serious work on this project, and I never had a further opportunity to benefit from his wisdom.

Eleven years have elapsed since the 29th American Edition appeared in 1973. Recognizing the special regard held for this book by generations of American anatomists, I felt that it was of special importance for me to understand the views held by many of my esteemed colleagues in the United States and Canada about the current usefulness of the book and how it might be altered or improved. Many informal discussions almost invariably pointed to the lasting value of having available for student and profes-

sional use a comprehensive anatomic treatise that is organized by systems. Many valuable suggestions from these conversations have been incorporated in this edition and my appreciation is extended to my many friends for their interest and their patience with my many questions.

Nearly two thirds of the chapters in this edition have been thoroughly revised and the remainder have been edited. The chapter on Developmental and Gross Anatomy of the Central Nervous System has virtually been rewritten as have extensive sections in at least ten other chapters. Many hundreds of new paragraphs and pages have replaced those of the 29th edition and, thus, numerous subjects have received some expanded attention and updating. To list them all here would not be appropriate, but a few of these are: certain aspects of the new cellular biology and embryology; the physical features and properties of bone and its formation; the development, classification and movement of joints; the form, attachment and actions of muscles, as well as the structure of skeletal and cardiac muscle; the vascular supply to the central nervous system; and the development of veins and lymphatics. Certainly, due to time limitations, many subjects did not get the attention they deserved, and thus, much still needs to be done in subsequent editions. Because the value of this book is essentially its information on the gross anatomy of the human body, it was not the intention of the editor to offer the reader comprehensive treatments in the fields of embryology, microscopic anatomy, physiology, and neuroscience. Excellent texts written by scholars expert in these subjects already exist, and to recount detailed features of their disciplines here is unnecessary and would have been presumptuous.

I have attempted to retain the classical style of the text, long considered one of the most elegant examples of descriptive scientific literature. In the extensively revised chapters, however, few paragraphs remain totally intact. I have tried to match the new with the old, to simplify some of the more complex sentence structure in order to clarify meaning, and to maintain a uniformity of prose. I hope that at least to some extent this effort has been successful.

A nearly complete change has been introduced in the headings within the chapters, yet the chapter subjects remain the same.

Using color print for various headings and subheadings will make it easier to find pertinent information on structures that in the past had to be identified by bold print within the paragraphs. In this respect, the student who must study and the practitioner who more quickly seeks information may both find the format of this edition beneficial. Additionally, the entire text has been reset and hundreds of more modern references and others that have proved valuable over time have been added to the reference lists at the end of each chapter. Many citations, in addition to those used in the text, have been made available for readers who require more knowledge than this book attempts to offer.

A significant number of new figures, never before published, have been introduced into this edition, along with numerous others borrowed from various sources. Many of the latter have come from original journal articles. The labels on most of the figures have been replaced with type that is easier to read. Certain older, less effective figures have either been eliminated or replaced by drawings that illustrate more clearly the subject matter. I believe the publishers should be commended for having done an excellent job in abiding by the principle to modernize the information and format and yet retain the classical look of this oldest (now 125 years), continuously used textbook in biomedical science.

Grateful acknowledgment must go to the many friends and colleagues who have contributed to this new edition, and my heartfelt appreciation is extended to so many authors and publishers who have allowed the reproduction of figures from their works or copyrighted properties. Especially mentioned, however, should be Professors Helmut Ferner and Jochen Staubesand, editors of Benninghoff and Goerttler's *Lehrbuch der Anatomie des Menschen*, published by Urban and Schwarzenberg in Munich, from which a considerable number of figures

were taken. Along the way, I have benefited greatly from the advice, suggestions, or contributions on one subject or another from Professors Leslie B. Arey, Malcolm B. Carpenter, James D. Collins, Jack Davies, George E. Erikson, Fakhry G. Girgis, W. Henry Hollinshead, Lawrence Kruger, Lee V. Leak, Raymond J. Last, David S. Maxwell, Keith L. Moore, Charles R. Noback, Keith R. Porter, Nabil N. Rizk, Charles H. Sawyer, William F. Windle, Luciano Zamboni, and the late Elizabeth C. Crosby and Jan Langman.

Many others, as well, have contributed greatly to the work of this revision. Among those who deserve special mention and much praise are Jill Penkhus, who created much of the new artwork for this edition; Dr. Charles F. Bridgman, who allowed the use of several of his drawings made of brain dissections prepared by the late Professor A. T. Rasmussen; Thomas Colaiezzi, at Lea & Febiger, who handled production; Howard N. King, who designed this new edition; Anne Cope who prepared the index; Dr. Caroline Belz Caloyeras, whose dedicated assistance with typing and editing was absolutely essential for this book to have appeared; and Dorothy Di Rienzi and, earlier, Mary Mansor of Lea & Febiger, who copy-edited all of the chapters. My appreciation also is extended to John F. Spahr and George Mundorff of Lea & Febiger who suggested that I undertake the work on this edition and then patiently waited for its completion.

Most importantly, I wish to offer my gratitude to Julie, my wife, who through the years has made her special contributions to whatever work I have undertaken. Her heartening and unfailing encouragement to me and her belief in the fundamental objectives of education have been my inspiration and have lightened the thousands of hours spent on this book.

CARMINE D. CLEMENTE

# Contents

## 1. Introduction

Terms of Position and Direction	2
Terms for Movements at Joints	4
Nomenclature	4
Approaches to the Study of Anatomy	5

## 2. Cytology and Embryology

The Cell	7
Cell Division	11
The Spermatozoon	21
The Ovum	23
The Development of the Embryo	34
Early Growth of the Embryo	36
Fetal Membranes and Placenta	51
The Placenta	58
The Growth of the Embryo and Fetus	61

## 3. Surface and Topographical Anatomy

The Head	69
The Neck	73
The Back	79
The Thorax	80
The Abdomen	85
The Perineum	96
The Upper Limb	98
The Lower Limb	107

## 4. Osteology

Ossification and Skeletal Development	114
Ossification	114
Skeletal Development	119
Axial Skeleton	126
The Vertebral Column	127
The Thorax	147
The Skull	158
The Appendicular Skeleton	225

Bones of the Shoulder Girdle and Upper Limb	226
Bones of the Lower Limb	261
Sesamoid Bones	304
Comparison of the Bones of the Hand and Foot	305
Histologic Structure of Connective Tissues	306
Connective Tissue Types	308

## 5. The Joints

Development of the Joints	329
Classification of Joints	330
Fibrous Joints	330
Cartilaginous Joints	333
Synovial Joints	333
Movements at Joints	335
Structures of Synovial Joints	336
Articulations of the Axial Skeleton	338

## Introduction

In ancient Greece, at the time of Hippocrates (460 B.C.), the word anatomy, *Ἀνατομή*, meant a dissection, from *τομή*, a cutting, and the prefix *ἀνά*, meaning up. Today anatomy is still closely associated in our minds with the dissection of a human cadaver, but the term was extended very early to include the whole field of knowledge dealing with the structure of living things.

The history of anatomy is one of the most exciting sagas in the ascent of human civilization. Since the subject deals with the structure of the body, it has lured some of the greatest minds not only to contemplate the nature of man, but to discover first hand by the method of dissection how the human being is put together. However, religious and other social pressures and taboos over the centuries made dissection of the human cadaver frequently a dangerous and secret activity. The study of the structure of the human body was the first of the medical sciences, and from it have derived all the rest. Even before human dissection was practiced by Herophilos and Erasistratos (300–250 B.C.), Aristotle (384–323 B.C.) dissected animals, wrote a treatise on their anatomy, and laid the groundwork for a scientific study of their form and structure.

Today it is considered that the greatest contributor to the subject matter of human anatomy was a young Flemish physician from Brussels who worked in Padua, Italy

**FIG. 1-1.** Andreas Vesalius (1514–1564). This figure was copied from the second edition of Vesalius' *De Humani Corporis Fabrica*, published in 1555. Having also appeared in the first edition (1543), it illustrates Vesalius during his late twenties and is still the only authenticated portrait of him known to exist.

during the height of the Renaissance. In 1542, at the age of 28, Andreas Vesalius, breaking boldly from the millennia and the prevailing traditions of Galen, published his great treatise *De Humani Corporis Fabrica* (Fig. 1-1). His work was so impressive and accurate that his books became the principal texts used by students of medicine for the next 200 years. Vesalius had substituted observation by dissection for authoritarianism, thereby grounding his findings on a scientific basis. Anatomy has therefore become the branch of knowledge concerned with **structure** or **morphology**. Our fund of anatomical information has been increased greatly during the last three or four centuries by the study of minute structure with the microscope, by following the development of the embryo, and by the addition of new and refined technical methods. The whole field of anatomy has become very large, and as a result a number of subdivisions of the subject

have been recognized and named, usually to correspond with a specialized interest or avenue of approach.

**Gross anatomy** is the study of morphology, by means of dissection, with the unaided eye or with low magnification such as that provided by a hand lens. The study of the structure of organs is **organology**. The study of the tissues is **histology**.

**Microscopic anatomy** is the study of structure with the aid of a microscope, and since it deals largely with the tissues, it is often called **histology**. Microscopic anatomy has another branch, the study of the cell, or **cytology**. An enormous increase in research into the finer structure of the cell has taken place in recent years, due to the adaptation of the **electron microscope** to the observation of ultrathin sections of the tissues.

**Embryology** or **developmental anatomy** deals with the growth and differentiation of the organism from the single-celled ovum to birth. These processes of development and maturation are also called **ontogeny**. It is impossible to understand clearly all the structures found in the adult body without some knowledge of embryology. Since human embryos, particularly the younger stages, are difficult to obtain for study, a large part of our knowledge has been gained from animals, that is, from **comparative embryology**. The second chapter in this book is devoted to a brief summary of **human embryology**. The development of each system is outlined in the appropriate chapters and sections.

**Comparative anatomy** refers to the study of the structure of all living creatures, in contradistinction to human anatomy which refers only to man. A comparison of all the known animal forms, both living and fossil, indicates that they can be arranged in a scale which begins with the simplest forms and progresses through various gradations of complexity and specialization to the most highly evolved forms. The unfolding of a particular race or species is called **phylogeny**. Many of the earlier stages of development in man and other higher animals resemble the adult stages of animals lower in the scale; hence it has been said that **ontogeny repeats phylogeny**. The study of comparative anatomy has contributed vitally to the understanding of human anatomy and physiology.

## Terms of Position and Direction (Fig. 1-2)

**THE ANATOMICAL POSITION.** The traditional anatomical position, which has been arbitrarily accepted, places the body in the erect posture with the feet together, the arms hanging at the sides, and the thumbs pointing away from the body. This position is used in giving topographic relationships, especially those which are medial and lateral in reference to the limbs. The muscle actions and motions at the joints are also given with reference to this position unless it is stated otherwise. It is particularly important that the anatomical position be remembered in descriptions using anterior and posterior, or the more general and ambiguous terms such as up, down, over, under, below, and above.

The **median plane** is a vertical plane that divides the body into right and left halves; it passes approximately through the sagittal suture of the skull, and therefore any plane parallel to it is called a **sagittal plane**. **Frontal planes** are also vertical, but they course at right angles to the sagittal planes. Since one frontal plane passes approximately through the coronal suture of the skull, they are also called **coronal planes**. **Transverse** or **horizontal planes** cut across the body at right angles to both sagittal and frontal planes.

**Ventral** and **dorsal** refer to the front and back of the body, and are synonymous with **anterior** and **posterior**. The use of these terms in courses of comparative anatomy may lead to some confusion for the student of human anatomy, since man's posture is erect. In the hands, **palmar** or **volar** is substituted for ventral or anterior. The sole of the foot is called **plantar**, while **dorsal** is retained for the top or opposite surface of both the hand and foot.

**Cranial** and **caudal** indicate the head and tail respectively, and are synonymous with **superior** and **inferior** when human subjects are in the anatomical position. In comparative anatomy the latter terms might be confused with dorsal and ventral when referring to four-footed beasts.

**Median** refers to structures along the midline or median sagittal plane of the trunk or limb.

Fig. 1-2. Diagrams illustrating the planes of the body and the terms of position and direction.

**Medial** and **lateral** refer to structures nearer or farther away from the median plane. It should be noted that the Latin word "medius" means middle, not medial. The Latin word for medial is "medialis."

**Superficial** and **deep** indicate the relative depth from the surface, and are preferable to over and under, and above or below, since the latter may be confused with superior and inferior.

**Proximal** and **distal** indicate a direction toward or away from the attached end of a limb, the origin of a structure, or the center of the body. Proximal refers to a structure closer to the center of the body, while distal refers to a structure farther from the body center.

**External** and **internal** are most commonly used for describing the body wall, or the walls of cavities and hollow viscera. At times these terms may be synonymous with superficial and deep, or even with lateral and medial.

## Terms for Movements at Joints (Fig. 1-2)

**Flexion** is that action which approximates two parts of the body connected at a joint. Flexion of the forearm at the elbow joint approximates the forearm to the arm; flexion of the calf at the knee joint approximates the calf to the posterior thigh. **Extension** is the act of straightening a limb, thereby diminishing the angle formed by flexion. Thus, straightening the flexed forearm at the elbow joint is an example of extension. Flexion and extension are, therefore, antagonistic actions. **Abduction** is the movement of a limb or other structure away from the middle line. Elevating an upper limb from the anatomical position at the side of the trunk to any point more lateral is an example of abduction. The opposite action, i.e., returning the abducted limb toward the midline is called **adduction**. The movements of flexion, extension, abduction, and adduction may be sequentially performed in a manner by which the end of a limb describes a circle or a cone; this is called **circumduction**.

**Pronation** is that movement of the forearm by which the palm of the hand is rotated to a backward position when the upper extremity hangs by the side of the body in the anatomical position. The pronated hand will

rest palm down on the surface of the table. **Supination** is the opposite, i.e., the rotation of the hand so that the palm faces forward in the anatomical position. The supinated hand rests with its palmar surface upward on a table surface. **Rotation** is a revolving or turning movement of a limb or other structure, such as the back or head, around its long axis. Both **medial** and **lateral rotation** are commonly observed at the shoulder and hip joints. **Protraction** is the forward movement of a body part such as the jaw or shoulder. **Retraction** is the opposite, i.e., the backward movement of these structures. **Eversion** is the outward rotation of the sole (plantar surface) of the foot so that it faces laterally. Oppositely, **inversion** is the inward rotation of the sole of the foot resulting in the plantar surface facing medially.

## Nomenclature

Although the majority of the common anatomical names are derived from those used by the ancient Greeks, considerable disagreement and confusion have arisen because of conflicting loyalties to teachers, schools, or national traditions. Shortly before the end of the 19th century, however, the need for a comprehensive system of nomenclature was realized, and a commission of eminent authorities from various countries was organized for this purpose. The system devised by this commission was adopted by the German Anatomical Society in 1895 at its meeting in Basel, Switzerland, and it has since been called the **Basle Nomina Anatomica** or the **BNA** (His, 1895).

The **BNA** gives the names in Latin, and many nations, including the United States, and Great Britain, adopted it, translating the terms into their own language whenever desirable. The French anatomists, however, did not entertain this nomenclature with much enthusiasm, preferring their own quite ancient tradition. The British anatomists gradually found certain inaccuracies and inconsistencies with their time-honored tradition which favored human anatomy related to the arbitrary "anatomical position." They broke away from the **BNA** and adopted their own revision in 1933 which they called the **Birmingham Revision** or **BR**. Even the German anatomists became restless under the restrictions of the **BNA** adoption of the

"anatomical position" and preferred an attempt to establish a scientific language applicable to the comparative anatomy of vertebrates as well as to human anatomy. In 1937 the Anatomische Gesellschaft met in Jena and adopted a revision that is known as the **Jena Nomina Anatomica** or **INA**. The anatomists of the United States remained faithful to the **BNA**.

At the Fifth International Congress of Anatomists held at Oxford in 1950 a committee was appointed to attempt a new revision of anatomical names. This International Nomenclature Committee met at Paris in July 1955, and approved the **Paris Nomina Anatomica** or **PNA**.

This book utilizes the terms designated in the **PNA** except in a few instances where it has been abandoned deliberately in the interests of clarity. Since Latin is less familiar to students today than in the past, names are usually given in English with the official Latin name at times italicized in parentheses. Other recognized names are also added in parentheses.

**Anatomical eponyms**, that is, designations by the names of persons, are popular among clinicians and specialists. Many eponyms have been added to the other names in parentheses in order to expose the student to terms commonly used in clinical medicine.

## Approaches to the Study of Anatomy

**Human anatomy** may be presented from at least three points of view: (1) **descriptive** or **systemic anatomy**, (2) **regional** or **topographical anatomy**, and (3) **applied** or **practical anatomy**. This book is primarily concerned with systemic anatomy, but regional and applied anatomy are introduced when their use facilitates communication.

**SYSTEMIC ANATOMY.** The body is composed of a number of systems whose parts are related by physiological as well as anatomical considerations. Each system is composed of several organs or tissues whose combined functions serve the body uniquely. Thus, although the anatomy of the oral cavity is remarkably different from that of the stomach or duodenum, these organs are presented in the same section because they all contribute to the functions of the digestive system. Although the study of

anatomy is concerned primarily with morphology, the knowledge of structure becomes more understandable and of practical value if the close association between structure and function is continually considered.

The systems of the body are as follows:

The **skeletal system**, the study of which is called **osteology**, consists of bones and cartilage. Its function is to support and protect the soft parts of the body.

The **system of joints** or **articulations** (*arthrology*) allows for the movement of bones while they are held together by strong fibrous bands, the ligaments.

The **muscular system** (*myology*) forms the fleshy parts of the body and is responsible for the purposeful movements of the bones at the joints.

The **vascular system** (*angiology*) includes the **circulatory system** consisting of the heart and blood vessels and the **lymphatic system** which transports the lymph and tissue fluids.

The **nervous system** (*neurology*) includes the **central nervous system**, composed of the brain and spinal cord, the **peripheral nervous system**, consisting of nerves and ganglia, and the **sense organs**, such as the eye and ear. The nervous system controls and coordinates all the other organs and structures, and relates the individual to his environment.

The **integumentary system** forms a protective covering over the entire body and is composed of the skin, hair and nails.

The **alimentary system** is composed of the food passages and the associated organs and glands of digestion.

The **respiratory system** supplies the body with oxygen and eliminates the carbon dioxide which results from the metabolic processes in the cells. It is composed of the air passages and lungs.

The **urogenital system** includes the kidneys and urinary passages and the reproductive organs in both sexes.

The **endocrine system** includes the thyroid, suprarenal, pituitary, and other ductless glands which control certain bodily functions by secreting hormones into the blood stream.

**Splanchnology** is the term that applies to the study of all the internal organs, especially those in the thorax and abdomen.

An account of the anatomy of any system would be incomplete without consideration of the microscopic anatomy and embryology

of the organs in that system. Sections dealing with these fields are appropriately located in the text.

#### TOPOGRAPHICAL OR REGIONAL ANATOMY.

**Regional anatomy** deals with the structural relationships within the various parts of the body, e.g., the pectoral region or axilla. Students in the laboratory usually approach the subject of anatomy regionally because they dissect by regions rather than by systems. Although the acquisition and organization of anatomical knowledge are easier for beginners if followed by systems, students in the medical fields must continually be on the alert to learn the relationship of the various parts to each other and to the surface of the body, because the final purpose of their study is to visualize these relationships in living subjects. The recent introduction of new radiologic scanning techniques in the clinics has reemphasized the importance of

human dissection and of learning anatomical relationships. In addition to the dissection of the body, the study of topographical anatomy is carried out by the study of **surface anatomy**, **cross sectional anatomy**, and **radiographic or x-ray anatomy**.

**Applied anatomy** has a number of subdivisions, and is concerned with the practical application of anatomical knowledge in some clinical field or specialty. **Surgical anatomy**, **pathological anatomy**, and **radiological anatomy** are probably the largest fields.

**Physical anthropology** is closely related to human anatomy because it relies heavily on anatomical studies and measurements of man and other primates. It is more broadly a subdivision of human biology with particular emphasis on racial development, evolution, genetics, and paleontology.

## Cytology and Embryology

### The Cell

The human body is composed of structural units of protoplasm, called **cells**, which together with the intercellular material—especially plentiful in the bones, cartilages, tendons, and ligaments—form the tissues and organs. The individual cells are microscopic in size and occur in many gradations of shape and composition corresponding to their diversified functions (Figs. 2-1; 2-4). Every human being begins life as a single cell, the fertilized ovum. By the process of cell division there soon results a great increase in the number of cells. Additionally, by the processes of differentiation and metabolism, the tissues assume their varied functional states. All cells are composed of two parts: the outer soft, jelly-like **cytoplasm** surrounded by a limiting **plasma membrane**, and an inner **nucleus** composed of nucleoplasm which is surrounded by a **nuclear envelope**. During the interval between periodic divisions of the cell, the nucleus is in a

resting stage; during periods of division, the nucleus undergoes a series of changes called mitosis.

The **cytoplasm** of a cell appears homogeneous when seen with the light microscope, but in reality is very complex in structure. Within it are embedded many intracellular bodies and organelles (Fig. 2-1). Although most of these structures are recognizable with the light microscope, their finer details have only been seen through the higher magnifications of the electron microscope. Today it is appreciated that most cytoplasmic organelles are composed of delicate lipid-protein membranes. The outer surface of the cell, the **cell membrane (plasma membrane or plasmalemma)**, is frequently studded with microvilli or cilia or other surface specializations. Generally considered to be composed of two layers of protein between which rests a molecular layer of lipid, the cell membrane, or **unit membrane**, as it is now frequently called, appears trilaminar in structure. Functionally, the membrane is a very important structure because it controls the exchange of materials between the cell and its environment by osmosis, phagocytosis, pinocytosis, secretion, and other phenomena. A specialized region of cytoplasm called the **central body or centrosome** with its tubular **centrioles**, not always visible with the light microscope, usually lies at one side of the nucleus near the central part of the cell. It serves as a dynamic center with other intracellular structures such as the Golgi complex arranged around it, and it is especially important during cell division, as described on page 12. The **mitochondria**, visible in living cells seen with the phase contrast microscope, appear in the form of threads, rodlets, and granules. They are likely to be destroyed by the action of lipid solvents during the preparation of routinely preserved and stained microscope slides. Their internal organization has been revealed by the electron microscope (Figs. 2-1; 2-2). It has been demonstrated that mitochondria are composed of two membranes. One, a continuous outer limiting membrane, surrounds a second inner membrane whose surface area is enlarged by a series of folds called **cristae** (Palade, 1952, 1953). By their isolation with differential centrifugation, mitochondria have been shown to contain important enzymes necessary for the metabolic processes of oxidative phosphoryla-

tion. The **Golgi apparatus** (also called **Golgi bodies** or **complex**; Fig. 2-1) can be demonstrated in nearly all cells by special methods of preparation, but is seldom identifiable in living cells. With the electron microscope it has been shown to include large and small vacuoles, granules, and membranes associated with vesicles or clefts (Dalton and Felix, 1954). The Golgi apparatus appears to be importantly related to secretory functions in many cell types. Protein synthesized in the endoplasmic reticulum appears to move into the Golgi apparatus where it is "packaged" with a membrane and then discharged as a **vesicle**. The Golgi apparatus also seems to play a role in the secretion of mucus, hormones, lysosomes, and various intracellular granules. Electron micrographic studies have also shown that within the cell's cytoplasm can be found irregular networks of branching tubules with membranous walls which have been called the **endoplasmic reticulum** (Figs. 2-1; 2-4). Two types of endoplasmic reticulum have been identified, a **rough** or granular type and a **smooth** or agranular type. The rough endoplasmic reticulum contains particles called **ribosomes**, which are composed of basophilic **ribonucleic acid (RNA)** and protein, and either adhere to the membrane of the endoplasmic reticulum or lie free between the membranes. These structures appear to be importantly involved in protein synthesis. At times a number of these ribosomes are seen together in groups or clusters and, as such, are called **polyribosomes**. These granules, about 150 angstrom units (Å) in diameter (see white arrows, Fig. 2-1) may also be scattered throughout the cell (Palade, 1955). The agranular (smooth) endoplasmic reticulum does not contain basophilic ribosomes attached to its membranes and, therefore, usually is acidophilic in its staining property. It is found in large amounts in muscle cells as the sarcoplasmic

(From Fawcett, Amer. J. Anat., 1966.)

reticulum and in the cells of certain glands. Its function appears to be related to cholesterol and its derivative steroids as well as to certain cellular ionic mechanisms. Another cytoplasmic organelle is the **lysosome**. These electron dense bodies are also surrounded by membranes, and they contain certain hydrolytic enzymes that are capable of breaking down and "digesting" proteins and carbohydrates. Lysosomes also release their enzymes when a cell dies, and autolysis of the cell results. Other cellular organelles include microtubules, fibrils, and fibrillar material. The cytoplasm of the cell also contains many **cytoplasmic inclusions**, among which are granules of metabolic products such as glycogen, secretion granules, vacu-

oles, lipid inclusions, and inert or ingested material.

The **nucleus** of a cell in the intermitotic or resting stage is a spherical or elongated body surrounded by a thin **nuclear envelope** (membrane), which is interrupted by openings called **nuclear pores** (Fig. 2-3, A and B). It appears that through these pores certain substances may be interchanged between the **nucleoplasm** and the cytoplasm. The nucleoplasm contains several semisolid, basophilic staining bodies called nucleoli, which are variable in size in different cells. The nucleus also contains the genetic substance, **desoxyribonucleic acid (DNA)**, which in combination with the histone proteins forms a threadlike material called

**FIG. 2-4.** Schematic representation of a cell as seen with the light microscope and enlargements showing the fine structure of some of the cell constituents as revealed by electron microscopy. The endoplasmic reticulum is shown in three dimensions, other structures are in section. (From Copenhagen, *Bailey's Textbook of Histology*, Williams & Wilkins Co., 1964.)

**chromatin.** These strands may be brought out by staining the nuclei with various dyes, the one most commonly used being hematoxylin. The chromatin material is invisible in living resting nuclei except possibly with phase microscopy, but during cell division it is aggregated first into threads and then into refractive bodies called **chromosomes**. The process is called **mitosis** from the Greek word *mitos* (*μῖτος*) meaning thread. The chro-

mosomes of the germ cells carry the factors for the genetic or hereditary constitution of the individual.

### CELL DIVISION

Although the division of a cell by mitosis is a continuous process, it is the custom to identify four different stages: prophase, met-

aphase, anaphase, and telophase (Fig. 2-5). In preparation for the prophase, the **centrosome** divides into two parts which become oriented at opposite poles of the nucleus. During the **prophase**, the chromatin, which has been scattered throughout the nucleus, condenses into **chromomeres** which are scattered along a thread or **chromonema**. The threads are individual entities composed especially of desoxyribonucleic acid (DNA); they become condensed into more compact bodies, the **chromosomes**. During the **metaphase** the chromosomes become oriented in a plane, the **equatorial plate**, located midway between the two centrosomes, with a clear area, the **spindle**, leading toward each centrosome. At this time each chromosome has doubled. The two parts are named **chromatids** and are attached to each other at a particular site, the **centromere**. In late metaphase and early anaphase, each centromere divides. During **anaphase** the two chromatids of each chromosome separate, pulled apart by a spindle fiber leading to one or the other of the two centrosomes. The two sets of chromatids, now called daughter chromosomes, are grouped around the two centrosomes, which move to opposite ends of the cell. In **telophase** the chromosomes form a compact mass, lose their individuality, and disperse into the chromatin of the intermitotic nucleus.

The division of living cells cannot be observed in the intact body, even with high magnifications of the microscope. Harrison (1910), however, discovered that embryonic cells can survive and will divide on glass slides if they are placed in an appropriate medium with aseptic precautions. Since then many observations have been made using this method, known as *tissue culture*, on a wide range of different animal forms, including tissues from human fetuses, normal adults, and tumors. The following description (by W. H. Lewis) of cell division is based on observations of connective tissue cells or fibroblasts in cultures of tissues from chick embryos; descriptions of the process in other cells, such as those in the whitefish blastula, are virtually the same (Fig. 2-6, A to E).

**MITOSIS IN TISSUE CULTURE.** An hour or two before division begins, the centrosome material separates into two parts and is placed at opposite poles of the nucleus. During **prophase** (Figs. 2-5; 2-6, B), the chromatin is formed into threads and then into chro-

mosomes. The cell retracts its processes and tends to become spherical, with the nucleus centrally placed and mitochondria or other intracellular bodies arranged around it. Near the end of prophase, which takes about an hour, the nuclear membrane disappears and the chromosomes are released and move into the equatorial plane.

During **metaphase** (Figs. 2-5; 2-6, C), which lasts about six minutes, the chromosomes oscillate back and forth in short paths in the equatorial region, as if they were pulled first toward one pole and then toward the other by strings or fibers. Although these fibers are not visible in living fibroblasts, they are visible in many cell types, especially after fixation. Together with the chromosomes these fibers make up the **mitotic spindle**. Each chromosome splits longitudinally into two equal and similar daughter chromosomes.

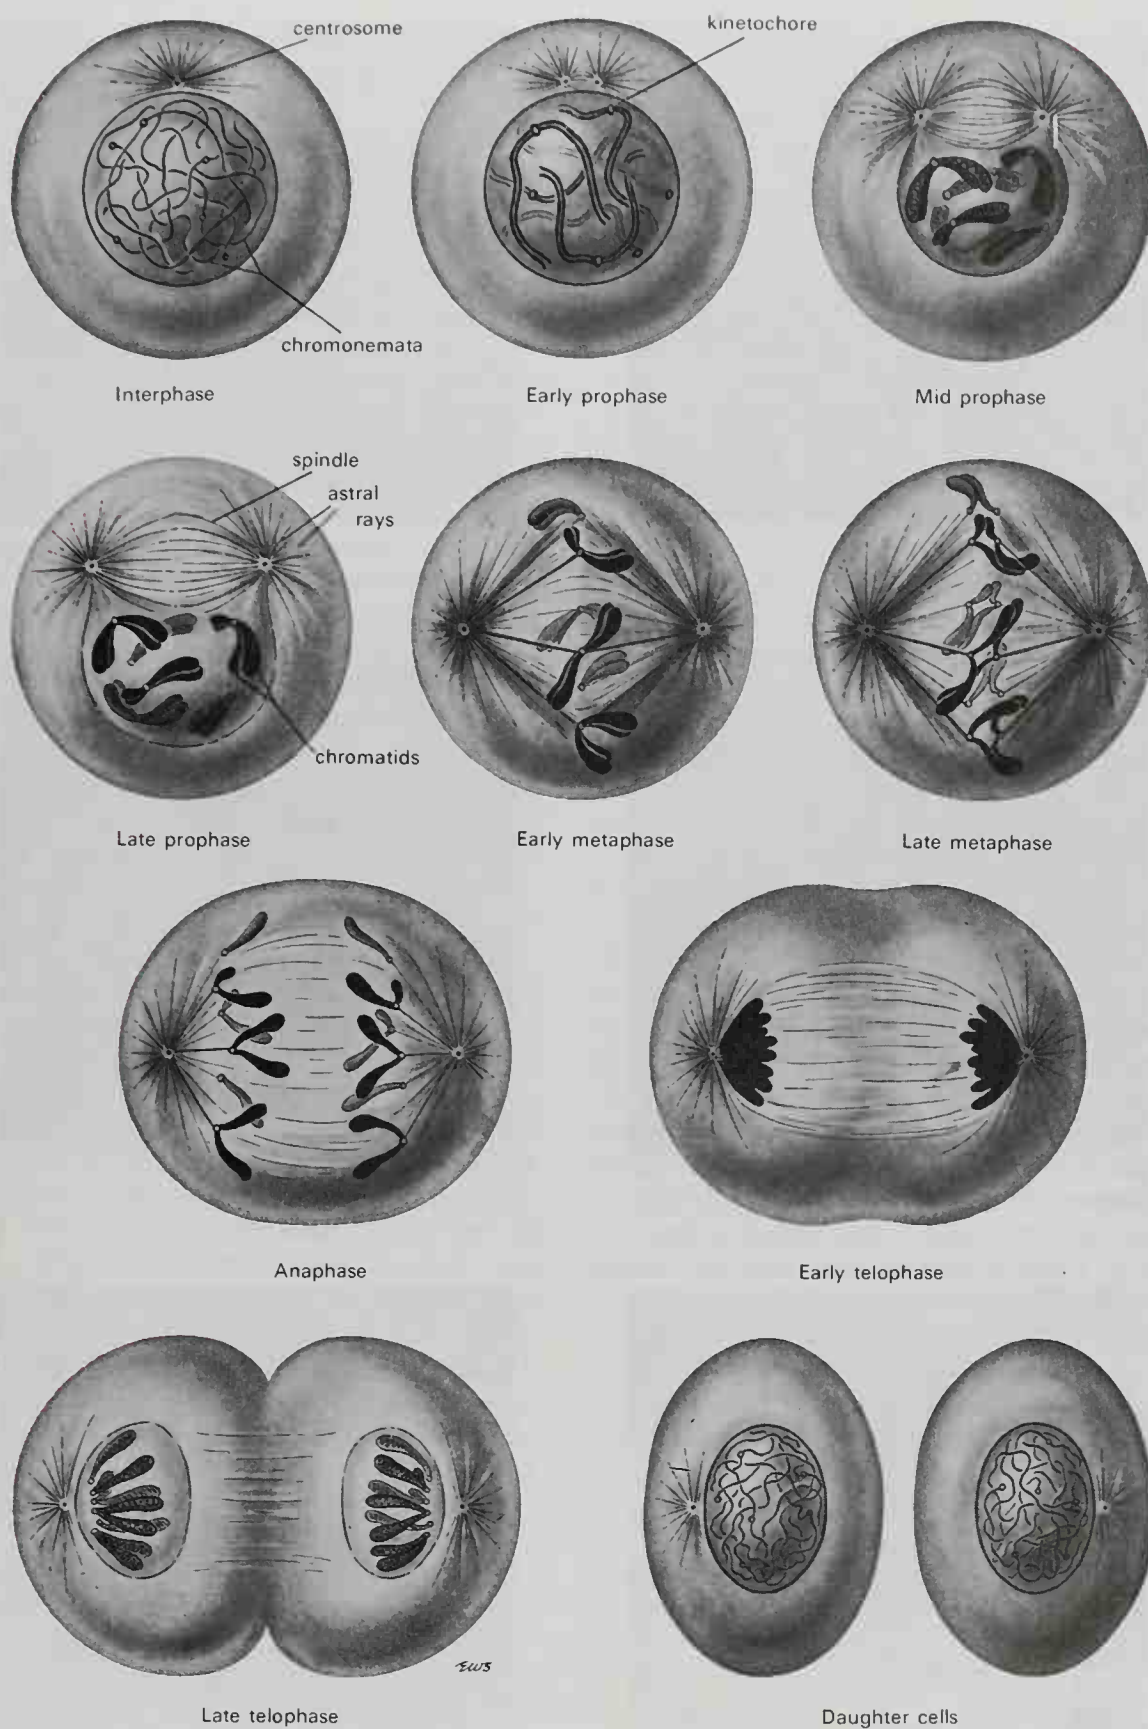

During **anaphase** (Figs. 2-5; 2-6, D and E), which lasts about three minutes, one set of daughter chromosomes moves to each pole of the spindle, or is pulled there by contraction of the spindle fibers, and is clumped into a compact mass. As the chromosomes approach the poles, the cell becomes elongated and a groove encircles it at the equator.

During **telophase** (Figs. 2-5; 2-6, F), which lasts about three minutes, the groove sinks farther into the cell, gradually pinching it into two daughter cells, which remain connected for a short time by a stalk. Each daughter cell receives approximately one-half the mitochondria, but the division of fat droplets and other intracellular bodies appears more haphazard. The chromosomes lose their identity in the compact mass of the daughter nuclei. The daughter nuclei slowly increase in size, as clear areas split the compact mass into granules, and a nuclear envelope forms. As the clear areas increase, the chromosomal granules become invisible except for those that become the nucleoli. It takes several hours for the nucleus to attain the final resting or intermitotic condition.

**AMITOSIS.** Direct division of the cell, or amitosis, has been described but probably does not occur under normal conditions. Degenerating cells may show **nuclear fragmentation** without division of the cytoplasm or the centrosome.

**Binucleate cells** are not uncommon, especially in certain organs, and are formed either by mitotic division of the nucleus with-

out cleavage of the cytoplasm, or by some process not clearly understood such as fragmentation.

### Chromosomes

In the last three decades, dramatic advances in electron microscopy, biochemical genetics, and cytogenetics have enhanced our understanding of the mechanisms involved in cell division and of the fundamental biochemistry of genetic material. Concepts have emerged as to the nature of the control exerted by the nucleus over the activities of the cytoplasmic organelles. Additionally, this knowledge has even extended into an appreciation of how and where these processes can go wrong, thereby elucidating better than ever before the mechanics of genetic mutation and the hereditary nature of certain diseases. The interdisciplinary fields of cellular and molecular biology are oriented toward closing the gap between the structure observed by the anatomist using the electron microscope and the molecular chains so beautifully unravelled and reconstructed by the biological and physical chemists.

Chromosomes are the unique biological structures responsible for the continuity of an animal species through its generations. Further, through their genetic material, chromosomes dictate the proper functional activities of every living animal cell. In each animal species there is a characteristic number of chromosomes. In man there are 23 pairs or 46 chromosomes. This number, i.e., 46 chromosomes, is known as the **diploid** number. In the nucleus of the human sperm or ovum the chromosome number is exactly half, or 23, and this is known as the **haploid** number. When the male gamete fertilizes the female gamete, the diploid number of 46 is

attained. Thus, each pair of chromosomes consists of a maternal and a paternal chromosome. The random distribution of maternal and paternal chromosomes is such that in the germ cells, during maturation, over 16,000,000 possible combinations can result in the daughter cells. Of the 23 pairs in man, 22 are called **autosomes** and the remaining pair are the **sex chromosomes** which can be identified under the microscope by their size and shape. The sex pair in all the cells of a male organism consists of a large X and a small Y chromosome (Fig. 2-8). The sex pair of a female contains two X but no Y chromosomes (Fig. 2-7).

**STRUCTURE OF CHROMOSOMES.** At metaphase just prior to cell division, each chromosome can be observed to consist of two identical strands of chromatin called **chromatids**. The chromatids are connected at a constriction in the chromosome called the **centromere** or **kinetochore**, and each will become a separate chromosome when the centromere divides. The location of the centromere allows for a descriptive morphologic classification of chromosomes (Fig. 2-9). When the centromere is located in the middle of the chromosome, the chromosome is referred to as **metacentric**. As such its **arms** are of equal length. A chromosome in which the centromere is situated somewhere between its midpoint and one of its ends is called a **submetacentric** chromosome. In such chromosomes one arm is somewhat longer than the other. When the centromere is located very close to the end of a chromosome, the term **acrocentric** is used in its description, and it follows that such a chromosome has one very short arm and one that is considerably longer. The short arm of a chromosome is called "p," for "petite," while the long arm is designated by the letter "q" (Fraser and Nora, 1975).

**FIG. 2-6.** Stages of mitosis in whitefish blastula.

A, Interphase: This is a "resting" stage during which the chromatin material appears dispersed, although it is thought that the chromosomes continue to maintain their individual integrity.

B, Prophase: Chromatin commences to aggregate into discrete threads. Asters develop around the divided centriole at each end of the cell, and the nuclear envelope disintegrates.

C, Metaphase: The chromosomes move into a horizontal equatorial plane. Each chromosome is attached to a spindle fiber at its centromere and begins to split into two chromatids.

D, Anaphase: Each pair of chromatids abruptly becomes pulled apart to form daughter chromosomes which move toward the poles of the spindle.

E, Late Anaphase: The spindle continues to lengthen and a constriction of the cell body begins to pinch the cytoplasm into two cells.

F, Telophase: Separation is virtually complete. The daughter cells, however, are still connected by a fine cytoplasmic stalk which eventually is broken. (From *Genes in Action*, The Upjohn Co., 1967.)

FIG. 2-7 (female) and FIG. 2-8 (male). Colchicine metaphase of human cells grown in vitro, showing chromosomes. (From Tijo and Puck, *Proc. Nat. Acad. Sci. (U.S.A.)*, 1958.)

**HUMAN KARYOTYPE OR IDIOGRAM.** In the study of human genetics, living cells from the blood or other tissues are prepared in a tissue culture that allows them to proliferate and divide by mitosis. When individual cells are found in the appropriate stage of division, that is, the metaphase, colchicine is added to the culture, and one of the cells is flattened out on a glass slide in order to separate the chromosomes (Figs. 2-7; 2-8). When examined under the microscope, the individual chromosomes can be identified and mapped or arranged in a diagram called a **karyotype** (Figs. 2-10; 2-11). At one time the terms **karyotype** and **idiogram** were used interchangeably, but now the word **karyotype** is used for a systematized arrangement to typify the chromosomes of an individual according to a standard classification. The term **idiogram** is now used to mean a diagrammatic representation of a karyotype that may be based on many observations and measurements (Roberts, 1963). Thus, an individual's karyotype may be compared with normal chromosomes, and if abnormalities are identified, they may point to the diagnosis of some hereditary aberration in the individual.

A standard system has now been adopted for the purpose of classifying the chromosomes composing a human karyotype. This classification was determined at international conferences held in Denver (1960) and in London (1963).

FIG. 2-9. The nomenclature of chromosomes. The centromere (site of attachment) of the chromosome lies either in the middle (metacentric), off center (submetacentric), or near the end (acrocentric). "p" designates the short arm, while "q" is the large arm of a chromosome. (From Fraser and Nora, *Genetics in Man*, Lea & Febiger, 1975.)

**Figs. 2-10 and 2-11.** Karyotypes of human chromosomes. (From Tijo and Puck, Proc. Nat. Acad. Sci. (U.S.A.), 1958.)

**GROUP 1-3** Large chromosomes with centromeres approximately in the middle. The three chromosomes can be readily distinguished from each other by their size and centromere position.

**GROUP 4-5** Large chromosomes with centromeres in the submetacentric position. Although these two chromosomes are more difficult to distinguish from each other, chromosome 4 is slightly larger.

**GROUP 6-12 AND THE X CHROMOSOME** Medium-sized chromosomes with centromeres in the submetacentric position. Chromosomes 6, 7, 8, 11, and X are more metacentric than are 9, 10, and 12. The X chromosome most resembles 6. This group presents the major difficulty in identification of individual chromosomes.

**GROUP 13-15** Medium-sized chromosomes with centromeres in the acrocentric position. Chromosomes 13 and 14 have satellites on the short arms.

**GROUP 16-18** Rather short submetacentric chromosomes. Chromosome 16 is more metacentric.

**GROUP 19-20** Short metacentric chromosomes.

**GROUP 21-22 AND THE Y CHROMOSOME**

Very short acrocentric chromosomes. Chromosomes 21 and 22 may have a satellite on their short arm.

#### CHEMISTRY OF CHROMOSOMES AND CHROMATIN.

Investigations into the biochemical nature of the genetic substance have resulted in one of the more significant and exciting advances in the history of biological science. It has now been accepted that chromosomes consist principally of deoxyribose nucleic acid (DNA) embedded within proteins which are largely histones in type. Based on observations made by Wilkins with the techniques of x-ray diffraction crystallography, a breakthrough occurred with the publication of a paper by Watson and Crick in 1953 in which it was proposed that the DNA molecule consists of two strands of nucleotide molecules wound together in the form of a double helix (Fig. 2-12, A). Additionally, the *in vitro* synthesis of biologically active or infective viral DNA by Goulian, Kornberg, and Sinsheimer in 1967 elucidated further the nature of the nuclear substance which was first separated from the nuclei of cells by Friedrich Miescher almost a century earlier in 1871 and called **nuclein**. In later years nuclein was renamed nucleic acid.

DNA is composed of a linear assemblage of molecules of desoxyribonucleotides. Each

**Fig. 2-12.** A, Diagram of a part of the double-stranded DNA molecule as proposed in the double helix model by Watson and Crick. The horizontal rods represent the pairs of bases which connect the two strands. The vertical line is the longitudinal axis around which the coils of the double helix twist. B, A diagram showing the single-ringed pyrimidine bases, cytosine (C) and thymine (T) along with the double-ringed purine bases, adenine (A) and guanine (G) which connect the two strands of the DNA molecule. The nitrogenous bases link with the sugar (S), desoxyribose, which in turn binds with phosphate groups (P) in an alternating pattern along DNA strands.

molecule of the nucleotide consists of either a large double-ring purine base (adenine or guanine) or a smaller single-ring pyrimidine base (cytosine or thymine), plus the sugar, desoxyribose, and a phosphate group (Fig. 2-12, B). The sugar of one molecule is attached to the phosphate of the next in each of the two strands. The critical aspect of the contribution by Watson and Crick was the manner in which the two strands of desoxyribose and phosphate are interconnected. Knowing that in DNA the amount of adenine always equals the amount of thymine and that the amount of guanine always equals the amount of cytosine, and realizing that their model had to give DNA the property of self-replication, they proposed that wher-

ever a two-ring adenine base is located on one strand, it is attached to a one-ring thymine base on the other. Additionally, they proposed that a guanine base on one strand is always connected to a cytosine base on the other strand. (Fig. 2-12, B). The bases were then proposed to be held together loosely by hydrogen atoms. In the authors' own words:

The novel feature of the structure is the manner in which the two chains are held together by the purine and pyrimidine bases. The planes of the bases are perpendicular to the fibre axis. They are joined together in pairs, a single base from one chain being hydrogen-bonded to a single base from the other chain, so that the two lie side by side. . . . One of the pair must be a purine and the other a pyrimidine

for bonding to occur. . . . If it is assumed that the bases only occur in the structure in the most plausible tautomeric forms (that is, with the keto rather than the enol configurations), it is found that only specific pairs of bases can bond together. These pairs are: adenine (purine) with thymine (pyrimidine) and guanine (purine) with cytosine (pyrimidine).

In other words, if an adenine forms one member of a pair, on either chain, then on these assumptions the other member must be thymine; similarly for guanine and cytosine. The sequence of bases on a single chain does not appear to be restricted in any way. However, if only specific pairs of bases can be formed, it follows that if the sequence of bases on one chain is given, then the sequence on the other chain is automatically determined.

It has been found experimentally that the ratio of the amounts of adenine to thymine, and the ratio of guanine to cytosine, are always very close to unity for deoxyribose nucleic acid. . . .

It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material (Watson and Crick, 1953).

**REPLICATION OF DNA.** The simplicity of the Watson-Crick model for the structure of DNA was also combined with a unique property, i.e., the molecular structure at any part of one strand dictated specifically the molecular structure of the other. With a separation of the hydrogen bonds, each of the two strands could become the molds for the **replication** of DNA because of the necessity of the divided strand to bind exactly as before with a specific sequence of bases. In this manner the model accounted for the requirement necessitated by genes, that they have the ability to duplicate themselves exactly. The process of separation of the two DNA strands at the site of hydrogen bonding therefore would allow each of the strands to act as a template against which to synthesize a new companion strand (Fig. 2-13). In this manner the original double helix could produce two exact replicas of itself, chemically identical in every respect, following the separation of the chromosomes at cell division.

**MECHANISMS OF GENE ACTION: TRANSCRIPTION.** Although chromosomes show little visible internal structure when viewed by conventional microscopes, it is now appreciated that the DNA component of chromosomes includes submicroscopic structures, which are spaced linearly along the DNA thread and are called **genes**. Genes can be

considered the centers for the control of particular hereditary traits. The nature of the genes' interactions with their environments (the cytoplasm of the cells) establishes the hereditary peculiarities or characteristics of an individual. It is called that person's **genotype**. Anatomically a gene is a section of the DNA molecule and is functionally involved in the determination of the sequential order of the amino acids, which form a single polypeptide chain of a protein.

The process by which the arrangement of the linear chemical groupings on the DNA molecule is communicated to the cytoplasm for the formation of proteins required for a cell's functions is called **transcription**, and the chemical language which has to be translated to understand this communication is called the **genetic code**. The number of possible differences in the sequential arrangement of the nucleotide bases provides DNA with an exceedingly high number of possible combinations, a property which the genetic material must have in order to account for the many different genes.

Another nucleic acid, **ribonucleic acid** or **RNA**, is present in larger quantities than DNA in cells known to be particularly active in protein synthesis. Unlike DNA, ribonucleic acid is found not only in the nucleus of the cell, but in the cytoplasm as well. It has been shown that the RNA found in the cytoplasm of cells is synthesized in the nucleus and moves from the nucleus to the cytoplasm. Although quite similar in chemical structure, RNA differs from DNA in three ways. RNA contains the sugar, ribose, instead of desoxyribose; generally RNA is a single chain while DNA is double-stranded; and RNA contains the pyrimidine base uracil instead of thymine.

In the process of transcription the double-stranded DNA separates as it would in DNA replication. Alongside of one of the two DNA strands (the master strand), however, nucleotides containing ribose (ribonucleotides) align in proper sequence to the DNA nucleotides. The RNA, now containing the coded sequence, separates from the DNA, leaves the nucleus through the pores in the nuclear envelope, and moves into the cytoplasm. As such it is called the **messenger RNA (mRNA)**. The synthesis of protein actually takes place in the ribosomes of the cytoplasm, and the mRNA becomes attached to

**FIG. 2-13.** A diagram illustrating the replication of the DNA molecule. The two strands of the old molecule separate and act as templates for the newly formed strands. In this manner the sequence of bases is copied exactly, thereby replicating the original molecule.

the ribosomes. In the eventual formation of a protein, two other types of RNA are involved. These are **ribosomal RNA (rRNA)**, a normal structural component of the ribosomes, and **transfer RNA (tRNA)**, which functions as the carrier of amino acids from

the rest of the cell's cytoplasm to the site of protein synthesis in the ribosomes. Thus, the genetically coded information along the DNA strand (gene) for the production of a specific polypeptide becomes transferred to cellular elements in the cytoplasm, which

not only are capable of recognizing the chemical code, but also are capable of producing the protein required.

**GERM CELLS.** For an individual to begin life and develop into an embryo, it is necessary for specialized cells, the germ cells from each sex, to be combined at fertilization. The female germ cell is the ovum; the male germ cell is the spermatozoon.

### THE SPERMATOZOON

The spermatozoa or male germ cells are produced in the testis and are present in the seminal fluid in enormous numbers. Each mature human spermatozoon is a highly specialized cell resembling a free-swimming protozoan and possessing a prominent head and a long tail (Figs. 2-14; 2-15). The length of the entire spermatozoon is 52 to 62  $\mu$ . The tail is subdivided into a middle piece, principal piece, and end piece. The **head** is a somewhat flattened oval body 4 or 5  $\mu$  long and 2 or 3  $\mu$  thick. The head is composed of a condensed nucleus, the anterior two thirds of which is covered by an **acrosomal cap** with an **acrosome** at the tip. Running the entire length of the tail is an **axial core** composed of filaments whose ultrastructure appears identical with that of a cilium. In the center of the axial core are two single filaments surrounded by nine uniformly spaced double filaments. The cylindrical **middle piece** surrounds the axial structures from the head to the ring-shaped annulus. It is 5 to 7  $\mu$  long, 1  $\mu$  thick, and contains a single layer of spirally arranged thread-like mitochondria. The **principal piece** is 45  $\mu$  long and  $\frac{1}{2}$   $\mu$  thick and is composed of a circular arrangement of dense fibers. In the **end piece** the axial filaments are covered only by the **plasma membrane** covering the entire spermatozoon. The axial filaments are assumed to be the contractile elements that provide the undulating motion of the tail. The development of the spermatozoa within the seminiferous tubules can be considered as a threefold process: (1) **spermatocytogenesis**, during which the primary germ cells replace themselves and produce primary spermatocytes; (2) **meiosis**, that phase during which the spermatocytes become spermatids, each containing the haploid number of chromosomes; and (3) **spermiogenesis**, during which the immature spermatids become transformed into mature sperm.

**SPERMATOCYTOGENESIS.** Among the epithelial cells lining the seminiferous tubules of the testis are found the primary male germ cells which are called the **spermatogonia**. By the process of mitosis these cells proliferate. Some of the daughter cells form more spermatogonia, while others migrate toward the lumen and enlarge into the **primary spermatocytes**. The primary spermatocytes then begin their process of **maturation** by dividing, at the first maturation division, into two secondary spermatocytes. Each **secondary spermatocyte** in the second maturation division divides into two spermatids. Thus, each primary spermatocyte provides four spermatids, all of which develop into motile spermatozoa (Fig. 2-16).

**MEIOSIS.** One of the most important aspects of germ cell maturation is the distribution of chromosomes and their constituent carriers of heredity, the genes. This takes place by a special type of cell division called **meiosis**. During the prophase of a usual somatic mitosis each threadlike chromosome initiates a longitudinal splitting. In the **first maturation division** of meiosis in the primary spermatocyte, however, the individual chromosomes do not carry the splitting to completion, and the two chromosomes of each pair except the sex chromosomes come into close union by a process known as **synapsis** or **conjugation**. The resulting chromosomal configuration is known as a **tetrad** from its quadruplicate appearance (Painter, 1923). The individual chromosomes of the synaptic pair, without splitting, separate from each other, and one chromosome of each pair goes to each daughter cell. As a result the number of chromosomes in each daughter cell is **reduced** to one half, or 23, in the secondary spermatocytes, one of which contains an X chromosome and the other a Y chromosome. In the **secondary maturation division** the chromosomes of each secondary spermatocyte now complete their splitting, and each divides into two spermatids. The result is four viable spermatids, each containing 23 chromosomes, the haploid number. Two of the spermatids contain X chromosomes while the other two contain Y chromosomes.

**SPERMIOGENESIS.** The differentiation of the spermatid into the mature sperm begins at one pole of the nucleus with the formation of a fluid-filled **acrosomal vesicle** from the Golgi complex. The acrosomal vesicle ad-

**FIG. 2-15.** Diagram of the structure of the human spermatozoon based on studies with the electron microscope. Most of the principal piece and end piece have been omitted. A, Depicted as though the cell membrane and cytoplasmic matrix had been removed. B, Diagrammatic cross sections showing the arrangement of the axial fibrils and their relation to adjacent structures. C, Diagram of a longitudinal section passing through the center of A. (From Fawcett, *Internat. Rev. Cytol.*, 1958.)

heres to the outer aspect of the nuclear membrane, and this becomes the future anterior tip of the sperm (Fawcett and Hollenberg, 1963). The acrosomal vesicle then loses its fluid and fits over the nucleus at the anterior end as a head cap with the acrosome at the tip. The centrioles migrate toward the opposite pole of the nucleus where a slender **flagellum** is forming. One of the centrioles forms the base of the flagellum which then elongates and develops its axial filaments. The other centriole forms a ring or annulus which migrates away from the nucleus to the caudal end of the middle piece, and the spiral mitochondrial sheath occupies the rest of

the middle piece. The residual cytoplasm is finally cast off, leaving the plasma membrane covering the entire mature spermatozoon.

## THE OVUM

The **human ovum** is a large cell, about 0.14 mm in diameter, and contains the visible internal structures found in most cells (Fig. 2-17). The nucleus with nucleolus and chromatin is known as the **germinal vesicle**. The cytoplasm contains a centrosome, mitochondria, granules, fat droplets, Golgi com-

Fig. 2-17. Mature human ovum. (Carnegie Institute Collection.)

plex, and yolk material. The ovum or **vitellus** is enclosed in a tough transparent membrane about 12  $\mu$  in thickness, named the **zona pellucida**. With the ovary, the mature ovum is contained in a spherical vesicle about 1 cm in diameter called an **ovarian** or **graafian follicle** (Fig. 2-18). The ovum is held at one side of the follicle by a mass of follicular cells named the **cumulus oophorus**; the follicular cells immediately around the zona pellucida are radially arranged and make up the **co-**

**rona radiata** (Fig. 2-17). While in the ovary and at the time of ovulation, the ovum completely fills the cavity of the zona, but it shrinks shortly after ovulation and a perivitelline space filled with clear fluid is developed.

**Ovulation** occurs when the mature graafian follicle ruptures through the outer wall of the ovary and the ovum is discharged into the peritoneal cavity. Normally it does not remain free in the peritoneal cavity because

Volume and surface area of ovum in cubic and square microns estimated by authors. ODZ: outside diameter of zona. IDZ: inside diameter of zona. DV: Diameter of vitellus (ovum) in microns.

\*Determined or estimated from illustrations and data in articles quoted.

**FIG. 2-18.** A cross section of the ovary showing numerous follicles in various stages of development. Stained with hematoxylin and eosin. 20  $\times$ . (From diFiore, *An Atlas of Human Histology*, Lea & Febiger, 1981.)

the fimbriated end of the uterine tube covers the point of rupture, and the ovum is immediately swept into the lumen of the tube, probably by ciliary action (Rock and Hertig, 1944). Although such a close relationship between the fimbriae and the ovary has been observed in many mammals, in the human female the ciliated epithelial cells of the oviducts increase significantly in height at ovulation, thereby increasing the assurance of the ovum's entrance into the uterine tube.

In the sexually adult ovulating woman, an ovarian follicle matures and ruptures from the ovary in a cyclical manner at intervals of about 28 days. Although there may be some variation in the exact date of ovulation during the menstrual cycle, typically the mature ovum is discharged 14 days prior to the expected date of commencement of the next menstruation. With ovulation there frequently is a small amount of hemorrhage accompanied at times by slight pain. The basal body temperature then rises  $0.5^{\circ}\text{F}$ , and in carefully recorded and charted studies, the temperature has been shown to remain elevated for about the next 14 days. The temperature lowers again during the next menstruation and remains down on the days of the new cycle prior to the next ovulation. It is presumed that the right and left ovaries alternate in the production of newly ruptured ova.

**MATURATION OF THE OVUM.** Before an ovum can be fertilized, it must reach a particular stage of maturation, which begins just prior to ovulation. During the **first maturation division**, the ovum, now known as the **primary oocyte**, divides into one large cell, the **secondary oocyte**, and one small cell which is known as the first **polar body** or **polocyte** (N.E. polocy<sup>tum</sup>) (Fig. 2-16). The secondary oocyte quickly initiates the **second maturation division** by forming a mitotic spindle, but it is arrested in the metaphase stage until after it escapes from the follicle and is penetrated by a spermatozoon. During the second maturation division, which can be completed normally only if the ovum is fertilized, a large **mature ootid** and a small **second polocyte** are formed (Figs. 2-16; 2-19). The first polocyte may or may not divide into two smaller polocytes.

**MEIOSIS.** When the ovum or primary oocyte undergoes the first maturation division, there is a reduction in the number of chromosomes in the same manner as in sperma-

togenesis (Fig. 2-16). The secondary oocyte and the first polar body both contain 22 autosomes and one sex chromosome: Since it is a female cell, the primary oocyte has two X chromosomes and the secondary oocyte also must have an X chromosome. When it undergoes its second maturation division, therefore, there must be only an X chromosome in the ootid and the second polocyte. It will be seen from this that every ovum from a ruptured follicle can provide only one fertilizable ootid and that it will have an X chromosome. Since there are equal numbers of spermatozoa with X chromosomes and with Y chromosomes in the ejaculate, there is an equal opportunity for the fertilized ovum to contain two X or an X and a Y chromosome and the genetic equality of the sexes is assured.

### *Fertilization of the Ovum*

Ovulation takes place in a woman with regular menstrual cycles approximately 10 to 14 days after the onset of the preceding menstrual flow or approximately 14 days before the expected date of commencement of the next menstruation. The released ovum immediately begins its course through the uterine tube. It must be met by sperm in the ampulla of the tube within approximately 6 to 12 hours or it will begin to show signs of degeneration and no longer be fertilizable.

**Fertilization** takes place when a spermatozoon enters the ovum (Fig. 2-19). Normally only one sperm takes part in the process; its entrance causes the peripheral layer of the ovum to change into the vitelline membrane, which prevents the entrance of additional sperm. It is thought that the spermatozoon undergoes important changes which allow it to achieve and penetrate the ovum. The acrosome of the sperm becomes perforated, and this appears to allow certain enzymes to escape, thereby creating a path for the sperm through the zona pellucida to the ovum cell membrane. The plasma membranes of the two gametes seem to fuse, and as the sperm head enters the ovum, the latter completes its second meiotic division and the second polar body is formed. Once the spermatozoon has penetrated the ovum, the tail portion separates, and the head and middle piece expand into the **male pronucleus** and the **centrosome**. The nucleus of the ovum, known as the **female pronucleus**, and the

**FIG. 2-19.** The process of fertilization in the ovum of a mouse. (After Sobotta, *Atlas und Lehrbuch der Histologie und mikroskopischen Anatomie des Menschen*, Lehmann, 1911.)

male pronucleus migrate toward each other, and, breaking down into their constituent chromosomes near the center of the cell, are combined into the new **segmentation nucleus**. The mitotic division of this nucleus and the cleavage of the cell produce the **two-cell stage** which is the beginning of the embryological development of the individual.

Fertilization restores the diploid number of chromosomes, since each of the gametes contains the haploid number and their junction achieves genetic completeness. Additionally, fertilization also results in the determination of the sex of the newly formed zygote. Since the ovum is an X-bearing gamete, fertilization by an X-bearing sperm results in an XX-bearing female zygote. In contrast, penetration and fertilization of the ovum by a Y sperm causes the formation of an XY-bearing male zygote.

#### **Development of the Fertilized Ovum**

Division of the fertilized ovum into the two-cell stage probably occurs 30 to 36 hours after fertilization. Hertig et al. (1954) have

recovered a two-cell human embryo surrounded by the zona pellucida and containing two polar bodies from a uterine tube. These first two cells, known as **blastomeres** (Figs. 2-20, B; 2-21), soon undergo division, and the process of **cleavage** or **segmentation** continues until a cluster of daughter cells, the **morula**, has been produced. During segmentation the ovum does not enlarge; the morula is about the same size as the single-celled ovum. The exact timing is not known, but probably two or three days are required for these five or six cleavage divisions, and while they are taking place the ovum makes its passage through the uterine tube.

**MORULA.** Although there is no visible difference between the early daughter cells, a segregation of materials and potencies takes place during cleavage, which first becomes evident in the morula (Fig. 2-20, E). By the fourth day two separate parts of the morula become recognizable, an outer layer of cells known as the **trophoblast**, and an inner cluster of cells, known as the **inner cell mass** or **embryoblast**. Together they form the **blastocyst**.

**FIG. 2-20.** Photographs of living eggs. 200  $\times$ . A, Fertilized one-cell mouse egg showing the zona pellucida, perivitelline space, ovum, first and second polar bodies (From Lewis and Wright, *Carneg. Inst., Contr. Embryol.*, 1935). B, Two-cell monkey egg. C, Four-cell stage of same egg, extra sperm in zona (From Lewis and Hartman, *Carneg. Inst., Contr. Embryol.*, 1933). D, Eight-cell rabbit egg. E, Rabbit morula (From Lewis and Gregory, *Science*, 1929). F, Early blastocyst, 76-hour mouse egg with a small amount of fluid.

**FIG. 2-21.** A two-celled human ovum recovered from the fallopian tube. Observe the prominent and closely adhering zona pellucida. Note one polar body between the two blastomeres at the upper margin of the cleavage plane and the other polar body below. 550  $\times$ . (From Hertig, Rock, Adams and Mulligan, *Carneg. Inst., Contr. Embryol.*, 1954.)

The **blastocyst** develops by the passage of fluid from the uterine cavity into the interior of the morula (Fig. 2-22). The trophoblast enlarges to form a vesicle, the center of which is a fluid-filled cavity called the **blastocyst cavity** or **blastocoele**. The cavity is surrounded by the trophoblast cells which multiply, spread out, and become flattened against the zona pellucida. This latter struc-

ture is thereby stretched into a thin membrane and disappears. The inner cell mass remains as a relatively small cluster of cells attached to the inner surface of the trophoblast at a region which is known as the **embryonic pole**. The blastocyst stage is reached soon after the ovum enters the uterus, where it remains free in the uterine cavity for an estimated three to five days.

**FIG. 2-22.** A, Blastocyst, 92-hour rabbit egg. Trophoblast and inner cell mass. 200  $\times$ . (From Lewis and Gregory, *Science*, 1929.) B, Blastocyst, nine-day monkey egg. Stained section. The zona has disappeared, the trophoblast is thin, and the inner cell mass small. 200  $\times$ . (From Carnegie Institute Collection.)

### Implantation

On the sixth or seventh day after fertilization, the blastocyst comes into direct contact with the uterine mucosa or endometrium and adheres to it. Since the zona pellucida has disappeared by this time, the trophoblast cells at the embryonic pole work their way into the endometrium by digesting the uterine tissue. By the eighth to tenth day the blastocyst has become a thickened invasive mass buried in the mucosa (Figs. 2-22; 2-23; 2-25). A thin wall of trophoblastic cells op-

posite the embryonic pole still protrudes into the uterine cavity (Figs. 2-23; 2-25). Changes in the endometrial wall and in the uterine glands following ovulation prepare the uterus for the reception of the blastocyst. Usually implantation occurs on the posterior wall of the uterus near the fundus.

By the twelfth day the embryo has become completely buried and the site of implantation in the endometrium has been closed over by the uterine epithelium (Figs. 2-24; 2-26). The trophoblast has formed a spongy mass which has broken into the walls of

**FIG. 2-27.** A human ovum embedded in the stratum compactum. Estimated age—13½ days. 35 ×. (Hertig and Rock, *Amer. J. Obstet. Gynec.*, 1944.)

thickened plate named the **embryonic** or **germ disc** (Figs. 2-23 to 2-28), from which the embryo proper will be developed. This two-layered or bilaminated disc consists of the columnar cells of the ectoderm, which lie adjacent to the amniotic cavity, and the flatter cells of the developing endoderm, which at first lie adjacent to the blastocyst cavity and then lie adjacent to the cavity of the primitive yolk sac. At about this time, scattered cells migrate outward from the border of the germ disc, forming a loose network of cellular processes which stretch across the blastocyst cavity and occupy the space between the trophoblast and the yolk sac, helping to hold the latter in place. This is the first representation of the **middle germ layer** or **mesoderm**, and since it occupies the blastocyst cavity rather than the germ disc, it is called the **extraembryonic mesoderm** (Fig. 2-26).

**EXTRAEMBRYONIC COELOM.** The first representation of the body cavity or coelom in the human embryo occurs very early, at a time when the amniotic cavity and yolk sac are still small and the germ disc has just been established (Fig. 2-26). The extraembryonic mesoderm, just beginning to form, spreads

out in a layer over the amnion and yolk sac, and around the inner surface of the trophoblast, as well as filling in the cavity of the blastocyst with a loose meshwork (Figs. 2-26; 2-27, labeled chorionic cavity). Between the layers of mesoderm covering the embryo and lining the blastocyst cavity, the loosely arranged mesodermal cells separate from each other and leave a space, the **extraembryonic coelom** (Figs. 2-26; 2-28; 2-31). The body cavity of the embryo proper is formed somewhat later and is at first independent of this extraembryonic coelom, but during the period when the yolk sac is being constricted at the body stalk, the two cavities do become confluent for a short time.

## Development of the Embryo

**EMBRYONIC DISC.** As the thickened layers of the germ disc grow out into a flat oval plate, they begin the formation of the embryo proper. The narrow end of the disc is attached at the **body stalk** and represents the caudal end of the embryo (Figs. 2-32; 2-33). The median line or axis in the caudal part of the embryonic disc is marked by the **primitive groove** (Figs. 2-29; 2-30,D; 2-33). Lying along the bottom of the primitive groove is an elongated mass of rapidly proliferating cells known as the **primitive streak** (Figs. 2-30, D; 2-33). The cells formed by this rapid proliferation spread out laterally between the ectoderm and endoderm as the **definitive mesoderm** of the embryo (**intraembryonic mesoderm**), part of which migrates forward as far as the cranial portion of the embryo. In this manner the third of the three primary germ layers, i.e., the mesoderm, forms between the other two (Fig. 2-30, B to D), thereby transforming the bilaminar disc into a three-layered or **trilaminated disc** (Fig. 2-30, A to D). Between the cranial end of the primitive streak and this anterior growth of mesoderm, the endoderm is thickened into a plate known as the **prochordal plate**. The endoderm and ectoderm remain in close contact at this point without the intervention of mesoderm, and the bilaminar area later becomes the buccopharyngeal membrane of the future stomodeum.

**THE NOTOCHORD.** At the cranial end of the primitive streak there appears a knot of ectodermal cells known as the **primitive (Henson's) node** (Figs. 2-29; 2-30, B), from which a

**FIG. 2-29.** Embryonic disc of 16-day-old human embryo surrounded by cut edge of amnion. Body stalk cut off at posterior end. Primitive groove overlies primitive streak. D, Primitive streak region. 50  $\times$ . (Heuser, Carneg. Inst., Contr. Embryol., 1932.)

**FIG. 2-30.** Transverse sections through presomite embryo shown in Fig. 2-29. A, Prochordal region. B, Notochordal region. C, Primitive node region. D, Primitive streak region. 100  $\times$ . (Heuser, Carneg. Inst., Contr. Embryol., 1932.)

strand of cells grows cranialward between the ectoderm and endoderm in the midline until it is blocked at the prochordal plate. This is the **notochordal process**, and it delineates the primitive axis of the developing embryo. Since the primitive streak must grow by a caudalward migration when the neural groove lengthens, the further growth of the notochordal process occurs by caudalward migration of the primitive node. During this migration the notochordal cells form

a flattened strand or plate which displaces the endoderm in the midline for a short time. The plate soon becomes a groove and then a tube, the **notochordal canal**. Cells bounding the floor of the notochordal canal separate to form openings so that the notochordal canal now communicates freely with the yolk sac. More caudally a temporary communication between the yolk sac and the amniotic cavity is established. This communicating channel is called the **neurenteric canal** and ex-

FIG. 2-31. Diagram illustrating early formation of allantois and differentiation of body stalk.

FIG. 2-32. Diagram showing later stage of allantoic development with commencing constriction of the yolk sac.

tends by means of the **primitive pit** (Fig. 2-29) through both ectoderm and endoderm at the primitive node. The primitive pit is generally considered homologous with the **blastopore** of lower vertebrates, a structure that is importantly involved in the processes of gastrulation in these animals. Certain early notochordal structures are transient, lasting only a short time before the somites are formed, but the notochord remains in the embryo as a solid rod of cells lying between the neural groove and the endoderm in the midline as a structural guiding axis for the growing vertebral column (Fig. 2-34). Only remnants of it persist in the adult.

#### EARLY GROWTH OF THE EMBRYO

**NEURAL TUBE.** In the middle of the third week (about the 18th day), the broad region

FIG. 2-33. Dorsal view human embryo 1.38 mm. in length, medullary groove open, about 18 days old. 52.5 X. (Ingalls, Carneg. Inst., Contr. Embryol., 1920.)

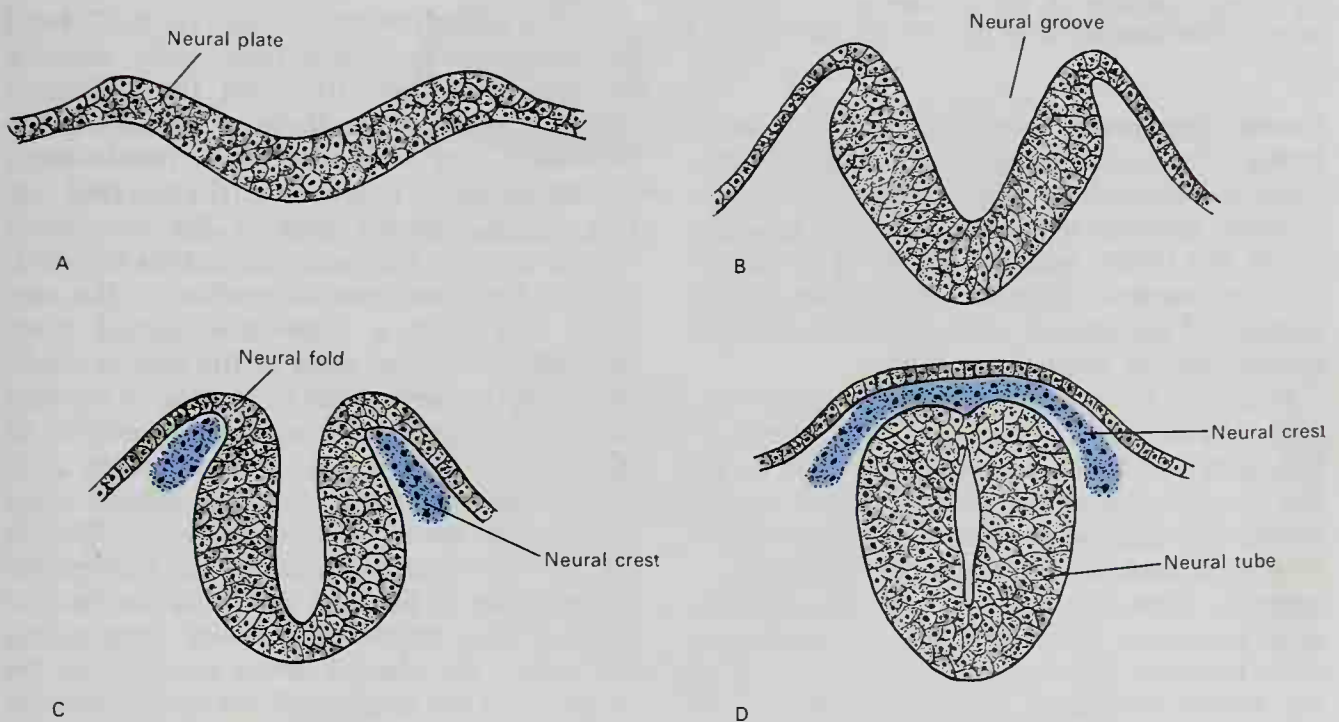

of ectoderm in front of the primitive streak of the embryonic disc becomes thickened and elevated into ridges on both sides of the midline, forming the **neural folds**, the first evidence of the nervous system (Fig. 2-35, A and B). As the primitive streak migrates caudalward, the neural folds become elongated (Fig. 2-33). Intervening between the neural folds is a longitudinal invagination called the **neural groove**. At about the end of the third week the crests of the neural folds rise into ridges, which gradually curve over the groove until they join, forming the **neural tube** (Figs. 2-35, C and D; 2-36). The closing of the neural groove occurs first along the early somites in the region of the future hindbrain (Fig. 2-36) and progresses both cranialward and caudalward. In the middle of the fourth week the cranial opening (anterior neuropore) of the neural groove finally closes at the future forebrain (Fig. 2-37). The caudal part of the neural tube is also temporarily open and is called the **caudal** or **posterior neuropore** (Fig. 2-37). It normally closes on the 26th or 27th day, about two days after the closure of the cranial opening.

While the neural folds are closing, neuroectodermal cells that lie along the dorsal edges of the neural plates on both sides fuse

**Fig. 2-34.** Transverse section through somite VIII (primitive segments) of the 14-somite human embryo shown in Fig. 2-37. 150  $\times$ . (Heuser, Carneg. Inst., Contr. Embryol., 1930.)

**Fig. 2-35.** Successive stages in the development of the neural tube. A, The neural plate develops from neuroectoderm, which probably is induced into differentiation by the underlying notochord and paraxial mesoderm. B, The neural plate invaginates to form a neural groove between the elevated neural folds on each side. C, The neural folds then converge, and at about the end of the third week begin to fuse to form the neural tube. D, As the neural tube fuses, certain neuroectodermal cells that do not participate in the formation of the neural tube develop into the neural crest and eventually form the sensory and autonomic ganglia, as well as other structures.

to form the **neural crest** or **ganglionic ridge** (Fig. 2-35, C, D). These cells then migrate lateralward and ventralward beside the neural tube, eventually forming certain ganglionic nerve and sheath cell components of

the cranial, spinal, and autonomic nerves (see Chap. 11 for more details).

The cranial end of the neural tube becomes expanded into a large vesicle with three subdivisions which correspond to the

**FIG. 2-36.** Dorsum of human embryo, 2.11 mm. in length. (After Eternod, *Actes helv. Sci. nat. Zurich*, 1896.)

future **forebrain** (prosencephalon), **midbrain** (mesencephalon), and **hindbrain** (rhombencephalon) (Fig. 2-45). The walls develop into the nervous tissue and neuroglia of the brain, and the cavity is modified into the cerebral ventricles. The more caudal portion of the neural tube develops into the spinal cord or medulla spinalis.

**PRIMITIVE GUT.** The embryo increases rapidly in size once the neural tube is established in the fourth week, but it does so by the overgrowth of the central region of the embryonic disc, while the margin of the disc, or line of junction between the embryo and amnion, stops growing and later even gradually becomes narrower. The constriction thus formed, corresponding in position to the future umbilicus, gradually pinches off the dorsal part of the yolk sac included in the disc, so that it becomes enclosed in the embryo proper as the **primitive gut** (Fig. 2-38).

Because of the rapid elongation of the neural tube, the embryo grows more rapidly in length than in width. This results in the cranial and caudal ends pushing out beyond the margin of the embryonic disc, and bending ventrally into **head** and **tail folds** (Figs. 2-37; 2-38). At the cranial end the forebrain grows beyond the **buccopharyngeal membrane** curving over the developing heart.

The diverticulum of the primitive gut, which occupies the head, is known as the **foregut**. Its most cranial extremity becomes the **buccopharyngeal membrane**, which marks the location of the future opening of the mouth, the **stomodeum** (Fig. 2-38). The caudal end of the embryo is at first connected to the chorion by a band of mesoderm called the body stalk, but with the formation of the tail fold, the body stalk is moved into the position of the **umbilicus**, and a diverticulum of the yolk sac called the **hindgut** is formed. The continuation of the hindgut caudally is a dilated cavity called the **cloaca**. For a time the opening into the yolk sac between the foregut and the hindgut remains wide, but the communication is gradually reduced to a slender tube known as the **vitelline duct** or **yolk stalk** and the yolk sac itself, being rudimentary, remains a small pear-shaped sac.

### **Mesoderm and Somites**

At the primitive streak stage (16 to 17 days) intraembryonic mesodermal cells migrate forward and laterally from the primitive streak on both sides, thereby separating the ectoderm and endoderm and transforming the bilaminated disc into a trilaminated one (Fig. 2-39). Certain cells of the mesoderm which migrate forward join across the midline in the most cranial portion of the embryo and form a horseshoe-shaped plate around the cranial ends of the neural folds. At about the time of the formation of the first somite (Fig. 2-40), the cells in the interior of this newly formed plate separate from each other, leaving small vesicles which soon coalesce to form a U-shaped cavity. This is the earliest representative of the **embryonic body cavity** or **coelom**, which is destined to become the **pericardial cavity** (containing the heart), the **pleural cavity** (containing the lungs), and the **peritoneal cavity** (containing the abdominal viscera). In the cardiogenic area the mesoderm of the outer coelomic wall becomes the **parietal pericardium** and, combined with the overlying ectoderm, is known as the **somatopleure**. The mesodermal cells of the inner wall of the coelom will form the **myocardium** and **epicardium** of the heart and, combined with the endoderm, are called the **splanchnopleure** (Fig. 2-34).

The median portion of the pericardial coelom expands greatly to accommodate the rapidly enlarging heart. As the rim of the embryonic shield is contracted in pinching

**FIG. 2-37.** Lateral view of a 14-somite human embryo. 50  $\times$ . (Heuser, *Carneg. Inst., Contr. Embryol.*, 1930.)

**FIG. 2-38.** Human embryo about 15 days old. Brain and heart represented from right side. Digestive tube and yolk sac in median section. (After His, *Anatomie menschlicher Embryonen*, F. C. W. Vogel, 1880-1885.)

**FIG. 2-39.** Cross-sectional diagram through an embryo of about 16 days. At this time mesenchymal cells migrate laterally from the primitive streak between the ectoderm and endoderm (entoderm). This mesenchyme forms the (intraembryonic) mesoderm, thereby changing the bilaminated disc into a three-layered one.

**FIG. 2-40.** Human embryo at about the end of the third week showing the beginning of the development of somites. The crown-rump length at this stage is about 2 mm. and subsequent somites develop in a craniocaudal sequence behind the first pair. (From Blechschmidt, *The Stages of Human Development Before Birth*, S. Karger, 1961.)

off the foregut, the heart and pericardial cavity protrude caudalward from the cranial ends of the neural folds, gradually becoming ventral to them with the foregut in between (see Figs. 7-1 to 7-4). Since the heart is the fastest growing part of the embryo at this time, it forms a prominent cardiac swelling between the yolk sac and the head fold of the embryo (Figs. 2-37; 2-38).

**VASCULAR MESENCHYME.** In the middle of the third week (15 to 16 days) and as the primitive pericardial cavity begins to expand, scattered cells separate from the mesoderm of the pericardial splanchnopleure and gather in the interval between the mesoderm and endoderm (Fig. 2-34). These cells are called **mesenchyme** (*mesenchyma*) or **angioblasts** and represent the primordium of the endothelial lining of the vascular system. They proliferate rapidly and in this cardiac region form a tubular sac, the **primitive endocardium** of the heart. A strand of cells grows out from the endocardium on either side of the cranial end of the foregut to become the primordium of the **first pair of aortic arches**. The latter join similar strands of cells lying along the notochord which are destined to become the **dorsal aortae** (Figs. 7-1 to 7-4).

At about this time also mesenchymal cells appear between the endoderm of the yolk sac and its covering of mesoderm. They proliferate rapidly, some gathering into groups to form aggregated masses and cords, which are called **blood islands**; others form strands that acquire a lumen and become the **yolk sac capillaries**. The capillaries join into larger vessels, which become the **vitelline or omphalomesenteric veins** leading to the heart. Similarly, the capillary systems in the **chorion** develop and become the **umbilical vessels** (Fig. 2-41).

**BLOOD.** The cells forming the blood islands of the vascular mesenchyme of the yolk sac are at first in compact groups. The fluid within the lumen of the capillaries, the **primitive blood plasma**, gradually separates the individual cells of the group into free cells, which are swept into the circulation when the final circuit is established. These are the **primitive hemocytoblasts**, and most of them rapidly acquire hemoglobin in their cytoplasm to become the **primitive erythroblasts** and **primitive erythrocytes** or red blood cells.

It has been theorized that the vascular endothelium, or perhaps even connective tissue cells of the later embryo, may revert

**FIG. 2-41.** Semischematic diagram shows basic vascular plan of human embryo at end of first month. For the sake of simplicity, the paired vessels are shown only on side toward observer. (Patten, *Human Embryology*, McGraw-Hill, 1968.)

into hemocytoblasts and produce hemoglobin-containing blood cells. Another theoretical point of view, however, is that tissue as highly specialized as hemoglobin-containing cells must logically come from a specific primordium. The mechanism for this would be the seeding of undifferentiated descendants of the primitive blood island hemocytoblasts in various tissues such as the liver, spleen, and bone marrow. In favor of this view are experiments with amphibian embryos in which the entire blood island was removed surgically. The resulting embryos grew into free-swimming larvae with complete vascular systems including hearts and livers but no erythrocytes. The larvae were kept alive for as long as 32 days with an increased oxygen supply. The circulation of clear plasma pumped by the heart could be detected by occasional passage of particles and non-erythrocytic cells in the capillaries of the gills (Federici, 1926; Goss, 1928).

The **beginning of circulation** occurs at about the eight-somite stage, during the early part of the fourth week (22nd day) in the human embryo. By this time the vascular lumen has become continuous from the endocardium, through the first aortic arches, aortae, yolk sac capillaries, and vitelline veins. The myocardium has become a muscular tube contracting with its own regular intrinsic rhythm. The cells within the blood islands become circulating hemocytoblasts and are swept through the vascular lumen by the primitive blood plasma and propelled by the pumping of the heart.

The changes that the heart undergoes during its development from the fusion of two symmetrically straight tubes into its more complex four-chambered structure are described in Chapter 7. This precocious development of the heart and the commencement of the circulation is necessary for the survival of the embryo because of the deficiency in stores of nutriment within the ovum. Since the circulation becomes established early in the fourth week, the circulatory system becomes the first functional system in the embryo. The growth of the umbilical vessels in the body stalk and the development of the chorionic villi soon establish the interrelationship between the embryonic and maternal circulations.

**SOMITES.** As the neural folds increase in size, the mesoderm along both sides of the notochord and neural folds expands into a column of cells, the **paraxial mesoderm** (Fig.

2-34). Early in the third week the cells of these columns become organized into paired blocks called **primitive body segments** or **somites**, which lie just under the ectoderm, where they are visible in the intact embryo and can be counted (Figs. 2-36; 2-37). From the somites are derived most of the axial skeleton, its associated musculature, and the skin dermis. This primitive segmentation of the embryonic mesoderm is retained as the muscular and skeletal segments of the mature organism. During development each individual segment also achieves its segmental nerve from the adjacently developing neural tube. The first pair of somites can be recognized on about the 20th day and differentiates in the future occipital region; the separation of new somites progresses in a caudal direction until eventually there are 42 to 44 pairs. The number of somites in each part of the human embryo are 4 occipital, 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 8 or 10 coccygeal. The first occipital and last few coccygeal somites regress and disappear. The other occipital somites become incorporated into structures of the head. Each of the remaining somites differentiates into three parts, a sclerotome, a myotome, and a dermatome (Fig. 2-42, D).

At first the somite contains a central cavity, called the **myocele**, surrounded by cells in a tightly packed epithelioid arrangement (Fig. 2-42, C). The ventromedial aspect of the somite soon breaks down into irregular-shaped cells which migrate toward the notochord giving rise to the **sclerotome**. These cells multiply rapidly, surround the notochord, and extend upward beside the neural tube to become the primordium of the vertebral column. The cells remaining in the dorsal and ventral parts of the somite next migrate into the region adjacent to the sclerotome, become elongated into myoblasts, and constitute the **myotome** from which the segmentally arranged musculature is developed. The remaining lateral part of the somite also breaks down; its cells migrate closely beneath the ectoderm as the **dermatome**, which provides the future dermis (Fig. 2-42).

While the somites develop from the medial portion of the paraxial mesoderm, the lateral portion spreads out into two thin sheets, one lying against the ectoderm, the other against the endoderm (Fig. 2-34). The space between the two sheets is part of the embryonic coelom (Fig. 2-42). The ectoderm,

**FIG. 2-42.** Drawings from transverse sections of pig embryos of various ages to show formation and early differentiation of somites. 150 $\times$ . A, Beginning of somite formation. B, Seven-somite embryo. C, Sixteen-somite embryo. D, Thirty-somite embryo. (Specimens from the Carnegie Institute Collection; figure reproduced from Crouch, *Functional Human Anatomy*, Lea & Febiger, 1972.)

with its layer of somatic mesoderm, is known as the **somatopleure** and forms the skin, muscles, bones, and fasciae of the body wall. The endoderm, with its layer of splanchnic mesoderm, forms the **splanchnopleure** from which develop the serous membranes of the future body cavities (Fig. 2-34). At the junction between the somites and the lateral mesoderm a special strand of cells appears which is known as the **intermediate cell mass** or **nephrotome**. It is the source of the future genitourinary system.

### Development of the Body Cavities

At the time of the commencement of somite formation, a cavity appears within the cardiogenic mesoderm at the cranial end of the embryonic disc. This cavity is the first indication of the **intraembryonic coelom** (Fig. 2-42, B). The coelom begins with the formation of scattered vesicles, which coalesce into a horseshoe-shaped cavity that is continuous across the midline in front of the forebrain, but is at first closed caudally in the region of the early somites. This cavity is the pericardial portion of the primitive coelomic cavity. The two lateral ends of the U-shaped cavity progress caudally, and in a short time become confluent with the extra-embryonic coelom on each side of the body of the embryo. As segmentation of the me-

dial portion of the paraxial mesoderm into somite formation continues, clefts occur within the mesoderm of the lateral plate resulting in the formation of the splanchnic and somatic mesoderm layers (Figs. 2-42, B; 2-43, A). The coelomic cavity forms between these layers. The splanchnic mesoderm with the underlying endoderm forms the intraembryonic splanchnopleure, while the somatic mesoderm with its overlying ectoderm forms the intraembryonic somatopleure (Fig. 2-43, B).

More rostrally as the pericardial cavity moves into its position ventral to the foregut by the formation of the head fold, a thick plate of splanchnic mesoderm comes to lie between the enlarged heart and the constricted portion of the yolk sac. This plate is known as the **septum transversum**. Through it the vitelline veins from the yolk sac reach the heart, and into it grows the diverticulum from the gut which forms the liver (Fig. 2-41). The more caudal parts of the coelom remain as narrow extensions on each side of the foregut in the region of the somites. This narrowed portion of the coelom dorsal to the septum transversum is called the **pleural canal** because a little later diverticula from the foregut which develop into the lungs push out this canal and expand it into the pleural cavities (Fig. 2-44).

At this early stage, the coelomic cavity is continuous from the pericardial cavity

**FIG. 2-43.** Diagrammatic representations of cross sections through developing embryos to illustrate the migration of mesoderm laterally from the region of the primitive streak between the ectoderm and endoderm (entoderm). A, Through the primitive streak at about 16 days. B, Through the neural tube at a somewhat later stage of development, perhaps in the fourth week. (Modified from Arey, *Developmental Anatomy: A Textbook and Laboratory Manual of Embryology*, W. B. Saunders Co., 1974.)

around the heart, through the pleural canals around the lung buds, into the peritoneal cavity in the abdomen. Later the coelomic cavity is divided into the pericardial, pleural, and peritoneal cavities by the formation of two septa. One septum begins as a fold of tissue on each side from the cranial border of the septum transversum and the lateral body wall; it protrudes into the pleural canal cranial to the lung bud and is known as the **pleuropericardial fold**. Within this fold are found the **common cardinal vein** and the **phrenic nerve**. The fold continues to grow outward until it completely closes the canal as a septum, separating the pericardial cavity from the pleural cavities (Fig. 2-44).

The second fold is more caudally placed and appears at the lower part of the septum transversum in the region where the common cardinal veins (*ducts of Cuvier*) open into the sinus venosus at the base of the heart. This fold, known as the **pleuroperitoneal fold**, is also paired, and it grows dorsally from the septum transversum. As the growing lung buds expand the thoracic cavities at both sides of the heart, the pleuroperitoneal fold contributes an important part of the tissue that forms the diaphragm. Eventually the diaphragm closes off the coelom and separates the pleural cavities from the peritoneal cavity.

### The Branchial Region

**PHARYNGEAL POUCHES AND BRANCHIAL OR VISCERAL ARCHES.** In the lateral wall of the anterior foregut or pharynx there develops during the 4th week a series of alternating depressions and ridges visible on each side of the embryo. The depressions are called the **pharyngeal pouches**, of which five pairs appear (Fig. 2-41); each of the upper four pouches is prolonged into a dorsal and a ventral diverticulum. On the external surface of the embryo, corresponding indentations of the ectoderm occur, forming what are known as the **branchial** or **outer pharyngeal grooves** (Fig. 2-45, shown but not labeled). The grooves separate a series of rounded bars or arches, the **branchial** or **visceral arches**, in which thickening of the mesoderm takes place (Figs. 2-45; 2-47). The dorsal ends of the branchial arches are attached to the sides of the head, while the ventral extremities ultimately meet at the

**Fig. 2-44.** Figure obtained by combining several successive sections of a human embryo of about the fourth week. The upper arrow is in the pleuroperitoneal opening, the lower in the pleuropericardial. (After Kollman, *Handatlas der Entwicklungsgeschichte des Menschen*, G. Fischer, 1907.)

midline of the neck. In all, six arches make their appearance, but of these only the first four are visible externally. The fifth and sixth branchial arches are more rudimentary and less well defined and can be seen only on the inner surface of the pharynx. The first arch is named the **mandibular**, and the sec-

**Fig. 2-45.** Embryo of the fourth week showing pharyngeal grooves between visceral arches. (His, *Anatomie menschlicher Embryonen*, F. C. W. Vogel, 1880-1885.)

**Fig. 2-46.** Head end of human embryo, about the end of the fourth week. (From model by Peter, *Atlas der Entwicklung der Nase und des Gaumens beim Menschen*, G. Fischer, 1913.)

ond the **hyoid**; the others do not have distinctive names and are referred to numerically (Fig. 2-46). The mandibular and hyoid arches are the first ones to appear and are recognizable in the 14-somite stage (Fig. 2-37). In each arch a cartilaginous bar, consisting of right and left halves, is developed, and with each of these there is one of the primitive aortic arterial arches. Additionally, each arch contains a primordium which will de-

**Fig. 2-47.** The floor and lateral walls of the pharynx of a four-week embryo showing the pharyngeal pouches as depressions between the pairs of branchial arches. (Head end of same embryo shown in Fig. 2-46.)

velop into muscle tissue, and receives nerves on each side which grow into the arch from the developing nervous system.

The **mandibular arch** lies between the first branchial groove and the stomodeum (Fig. 2-45). This first branchial arch is associated with the development of the face, and from it develop the lower lip, mandible, muscles of mastication, and anterior part of the tongue. Its cartilaginous bar is formed by what are known as the right and left **Meckel's cartilages** (Figs. 2-48; 4-14). The dorsal end of each cartilage, related to the developing ear, becomes ossified and forms two bones of the middle ear, the **incus** and the **malleus**. The ventral ends of each cartilage meet in the region of the symphysis menti, and whereas most of the cartilage disappears, the portion immediately adjacent to the malleus is replaced by fibrous membrane and becomes the **sphenomandibular ligament**. From the connective tissue covering the remainder of the cartilage, the greater part of the **mandible** is ossified. The triangular-shaped **maxillary process** grows forward on each side from the dorsal ends of the mandibular arch to form the cheek and lateral part of the upper lip. In addition to the muscles of mastication, the mylohyoid muscle, the anterior belly of the digastric muscle, and the tensors tympani and palati are derived from the mandibular arch. The nerve of the first arch is the **mandibular division of the trigeminal nerve**.

The **second or hyoid arch** assists in forming the side and front of the neck. From its cartilage are developed the styloid process, stylohyoid ligament, and lesser cornu of the hyoid bone. The stapes probably arises in the upper part of this arch. The muscles of facial expression along with the stapedius muscle, stylohyoid muscle, and posterior belly of the digastric muscle develop from the hyoid arch. The nerve of the second arch is the seventh cranial or **facial nerve**.

The cartilage of the **third arch** gives origin to the greater cornu of the hyoid bone. The ventral ends of the second and third arches unite with those of the opposite side, and form a transverse band, from which the body of the hyoid bone and the posterior part of the tongue are developed. The stylopharyngeus muscle and the upper pharyngeal musculature are derived from the third arch. The **glossopharyngeal** or ninth cranial

**Fig. 2-48.** Head and neck of a human embryo 18 weeks old, with Meckel's cartilage and hyoid bar exposed. (After Kölliker, *Grundriss der Entwicklungsgeschichte des Menschen und der Höheren Thiere*, von Wilhelm Engelmann, 1880.)

nerve is associated with the third branchial arch.

The ventral portions of the cartilages of the **fourth arch** unite to form the thyroid cartilage, while from the **fifth** and **sixth arches** develop the arytenoid, corniculate, cuneiform, and cricoid cartilages of the larynx. The musculature of the pharynx and larynx also forms from these more caudal arches, and the superior and recurrent laryngeal branches of the **vagus nerve** are associated with them.

The mandibular and hyoid arches grow more rapidly than those behind them, with the result that the latter become, to a certain extent, telescoped within the former, and a deep ectodermal depression, the **sinus cervicalis**, is formed on either side of the neck. This sinus is ultimately obliterated by the fusion of its walls; if this fails to happen, a **branchial cyst** results, or if the overgrowing mandibular and hyoid arches fail to fuse with the fifth arch below, a **branchial fistula** will develop.

From the first **branchial groove** the concha of the ear and external acoustic meatus are developed, while around the groove there appear, on the mandibular and hyoid arches, a number of swellings from which the auricle or pinna of the external ear is formed (Fig. 2-57). No traces of the second, third, and fourth branchial grooves persist.

The **first pharyngeal pouch** is prolonged

dorsally to form the auditory tube and the tympanic cavity; the closing membrane between the mandibular and hyoid arches is invaded by mesoderm, and forms the tympanic membrane. The inner part of the **second pharyngeal pouch** is named the **sinus tonsillaris**; in it the palatine tonsil is developed, above which a trace of the sinus persists as the supratonsillar fossa. The fossa of Rosenmüller or lateral recess of the pharynx is regarded by some as a persistent part of the second pharyngeal pouch, but it is probably developed as a secondary formation. From the **third pharyngeal pouch** the thymus arises as an endodermal diverticulum on either side, and from the fourth pouches small diverticula project and become incorporated with the thymus, but in man these diverticula probably never form true thymus tissue. The parathyroid glands also arise as diverticula from the third and fourth pouches. From the fifth pouches the **ultimobranchial bodies** originate and are enveloped by the lateral prolongations of the median thyroid rudiment; they do not, however, form true thyroid tissue, nor are any traces of them found in the human adult (see Development of Thyroid Gland, Chapter 18).

**NOSE AND FACE.** During the third week two sites of thickened ectoderm, the **olfactory areas**, appear immediately under the forebrain in the anterior wall of the stomodeum, one on either side of a region

termed the **frontonasal process** (Fig. 2-49). By the upgrowth of the surrounding parts these areas are converted into shallow depressions, the **olfactory pits**, which indent the frontonasal process and divide it into a **medial** and two **lateral nasal processes** (Fig. 2-50). The rounded lateral angles of the medial process constitute the **globular processes**. The olfactory pits form the rudiments of the nasal cavities, and the epithelium which lines the nasal cavities (except that of the inferior meatuses) is derived from the ectodermal lining of the olfactory pits. The globular processes are prolonged backward as plates, which are termed the **nasal laminae**. These laminae at first are some distance apart, but they gradually approximate and ultimately fuse to form the nasal septum. More superficially, the globular processes themselves meet at the midline, and form the **premaxillary bones**, as well as the **philtrum** or central part of the upper lip (Fig. 2-53). Between the globular processes, the depressed region of the medial nasal process forms the lower part of the nasal septum or **columella**. Above this is seen a prominent angle, which becomes the future apex of the nose (Figs. 2-50; 2-51), and still higher a flat area, the future bridge of the nose. The lateral nasal processes form the alae of the external nose.

Continuous with the dorsal end of the mandibular arch and growing forward from its cranial border is the triangular **maxillary process**, the ventral extremity of which is separated from the mandibular arch by a

V-shaped notch (Fig. 2-49). The maxillary process forms the lateral wall and floor of the orbit, and within it are ossified the zygomatic bone and the greater part of the maxilla. As development ensues, the maxillary process meets with the lateral nasal process, but is separated from it for a time by a groove, the **nasolacrimal sulcus**, which extends from the furrow encircling the eyeball to the olfactory pit. Ultimately the maxillary processes fuse with the lateral nasal and globular processes to form the lateral parts of the upper lip and the posterior boundaries of the nares (Figs. 2-52; 2-53). From the third to the fifth month the nares are filled by masses of epithelium, which then break down and disappear, thereby forming the permanent openings. Additionally, the maxillary process gives rise to the lower portion of the lateral wall of the nasal cavity. The roof of the nasal cavity and the remaining parts of its lateral wall (the ethmoidal labyrinth, the inferior nasal concha), as well as the lateral cartilage and the lateral crus of the alar cartilage of the external nose, are developed in the lateral nasal process.

The **primitive palate** develops by the fusion of the maxillary and nasal processes in the roof of the stomodeum (Fig. 2-54). The olfactory pits (also called **nasal pits**), which will become the nasal cavities, extend backward above the primitive palate. The posterior end of each pit is closed by an epithelial membrane, the **bucconasal (oronasal) membrane**, formed by the apposition of the nasal and stomodeal epithelium. As these mem-

**FIG. 2-49.** Facial region of a human embryo about 29 days old. (After His, *Anatomie menschlicher Embryonen*, F. C. W. Vogel, 1880-1885.)

**FIG. 2-50.** Head end of a embryo of 30 to 31 days. (From model by Peter, *Atlas der Entwicklung der Nase und des Gaumens beim Menschen*, G. Fischer, 1913.)

**FIG. 2-51.** Same embryo as shown in Fig. 2-50 with front wall of pharynx removed.

branes rupture, the **primitive choanae** or openings between the olfactory pits and the stomodeum are established.

The floor of the nasal cavity develops from a pair of shelf-like **lateral palatine processes**, which extend medialward from the maxillary processes (Figs. 2-54 to 2-56); these coalesce in the midline to constitute the entire palate, except for a small anterior portion, which is formed by the premaxillary bones. Two apertures persist for a time between the palatine processes and the premaxillae. In lower animals these persist as permanent channels while in the adult human palate the apertures are represented by the **incisive foramen** anteriorly in the hard palate. The union of the parts that form the palate commences anteriorly, the premaxillary and palatine processes joining in the ninth week, whereas the region of the future hard palate is completed by the tenth, and that of the soft palate by the end of the third month. By this time the **permanent choanae** are formed and are situated at the junction of the nasal cavities and the pharynx, a considerable distance posterior to the primitive choanae.

Failure in the union of the palatine processes with each other and with the nasal septum occurs about once in 2500 births (Moore, 1973). The resulting malformation is called

**cleft palate** and may manifest itself with varying degrees of severity. A mild deformity may be simply a small furrow in the soft palate, while in more severe cases, a large midline fissure may extend throughout the length of both the hard and soft palate. Perhaps the most important congenital deformity of the face is **cleft lip** (hare lip). This results through a failure in the fusion of the maxillary process with the corresponding

**FIG. 2-52.** Head of a human embryo of about eight weeks in which the nose and mouth are formed. (His, *Anatomie menschlicher Embryonen*, F. C. W. Vogel, 1880-1885.)

**Fig. 2-53.** Diagram showing the regions of the adult face and neck related to the frontonasal process and the branchial arches.

globular process (medial nasal process). Occurring about once in 900 births, it may be either unilateral or bilateral.

The nasal cavity becomes divided by the vertical **nasal septum**, which extends downward and backward from the medial nasal process and nasal laminae, and unites below with the transversely oriented palatine processes. Into this septum a plate of cartilage

extends from the inferior aspect of the ethmoid plate of the chondrocranium. The anterior part of this cartilaginous plate persists as the septal cartilage of the nose and the medial crus of the alar cartilage, but the posterior and superior parts are replaced by the vomer and perpendicular plate of the ethmoid. On each anteroinferior surface of the nasal septum, the ectoderm is invaginated to form a small blind pouch or diverticulum. These extend posteriorly for 3 to 5 mm, and each is supported by a tiny curved plate of cartilage. These pouches are called the **vomer-nasal organs** (of Jacobson) and in man they are rudimentary (Fig. 2-54). In certain other mammals, however, they apparently serve as accessory organs of olfaction, since their nerve filaments join the olfactory nerve.

### The Limbs

The limbs first appear in the fourth week as small elevations or buds at the side of the trunk. Unsegmented somatic mesoderm pushes into the limb buds and multiplies by division of its cells into closely packed cellular masses. During the sixth week, the forelimbs have grown anteriorly and lie lateral to the developing heart (Fig. 2-57). As the seventh and eighth weeks progress, the em-

**Fig. 2-54.** Frontal section of nasal cavities of a human embryo 28 mm. long. (Kollman, *Handatlas der Entwicklungsgeschichte des Menschen*, G. Fischer, 1907.)

**Fig. 2-55.** Primitive palate of a human embryo of 37 to 38 days. On the left side of the specimen the lateral wall of the nasal cavity has been removed. (From a model by Peter, *Atlas der Entwicklung der Nase und des Goumens beim Menschen*, G. Fischer, 1913.)

bryo becomes distinctly human in its form and the developing hands approximate the nose and chin (Fig. 2-58). The intrinsic muscles of the limbs differentiate *in situ*. The upper limb, developing in the caudal neck region, receives its innervation from the fourth cervical to the second thoracic spinal nerves. The lower limb bud develops in the lumbosacral region and receives nerves from the twelfth thoracic through the fourth sacral segments before the limbs migrate caudally.

The axial part of the mesoderm of the limb bud becomes condensed and converted into its cartilaginous skeleton. By its ossification the bones of the limb are formed. The three chief divisions of each limb can already be identified by the end of the sixth week. Furrows separate the upper limb into arm, forearm, and hand, and the lower limb

into thigh, leg, and foot (Fig. 2-57). The limbs are at first directed *inferiorly* nearly parallel to the long axis of the trunk, and each presents two surfaces and two borders. Of the surfaces, one, the future **flexor** surface of the limb, is initially directed ventrally; the other, the **extensor** surface, dorsally; one border, the **preaxial**, is oriented toward the cranial end of the embryo, and the other, the **post-axial**, toward the caudal end. The lateral epicondyle of the humerus, the radius, and the thumb lie along the preaxial border of the upper limb; and the medial epicondyle of the femur, the tibia, and the great toe lie along the preaxial border of the lower limb.

The limbs next undergo a rotation through an angle of 90 degrees around their long axes, the rotation being effected almost entirely at the limb girdles. Flexion increases at the elbow and knee, with the elbow pointing caudally and the knee cranially (Fig. 2-58). The upper limb rotates laterally and as a consequence its preaxial (radial) border is directed lateralward while the ventral (flexor) surface of the forelimb is turned cranially or anteriorly. The opposite (medial) rotation occurs in the lower limb. In the hindlimb, rotation directs the preaxial (tibial) border medially while the ventral (flexor) surface is oriented posteriorly.

#### FETAL MEMBRANES AND PLACENTA

The fetal membranes which protect and nourish the human embryo and which allow the elimination of metabolic materials are the **chorion** (which develops from the **trophoblast**), **amnion**, **yolk sac**, and **allantois**. The

**Fig. 2-56.** The roof of the mouth of a human embryo, aged about 2½ months, showing the mode of formation of the palate. (His, *Anatomie menschlicher Embryonen*, F. C. W. Vogel, 1880-1885.)

**FIG. 2-57.** Embryo of about six weeks. (His, *Anatomie menschlicher Embryonen*, F. C. W. Vogel, 1880-1885.)

**FIG. 2-58.** Human embryo about 8½ weeks old. (His, *Anatomie menschlicher Embryonen*, F. C. W. Vogel, 1880-1885.)

organ of metabolic transfer between the mother and fetus is called the **placenta** and includes a fetal portion derived from the chorion and a maternal part from the endometrial wall of the uterus.

In the early blastocyst stage, the trophoblast consists of a single layer of cells (Figs. 2-22 to 2-25). As the blastocyst becomes embedded in the endometrium of the uterus, two layers are formed in the trophoblast: The outer layer, rich in nuclei but with no evident cell boundaries, is called the **syncytiotrophoblast**; the inner layer (of Langhans) is cellular and is called the **cytotrophoblast** (Figs. 2-25 to 2-28; 2-59; 2-60). The trophoblast invades the tissue and vessels of the uterine wall and becomes converted into a thick sponge-like mass of strands consisting of cores of cytotrophoblast and outer coverings of syncytiotrophoblast. The walls of the uterine vessels lying in the path of the trophoblast become eroded, and maternal blood seeps into the spaces between the strands of trophoblast. These spaces are now called the **intervillous spaces** (Figs. 2-59; 2-60).

### Chorion

The outermost fetal membrane is known as the **chorion**. Its structure includes the strands of trophoblast that have become anchored to the uterine tissue and others that protrude into the intervillous space as primary villi (Figs. 2-59; 2-61). Its internal cavity (chorionic cavity or extraembryonic coelom) at first contains only fluid and loose strands of extraembryonic mesoderm. Later the amnion expands so rapidly that it encroaches upon the chorionic cavity until it comes into contact with the inner wall of the chorion, thereby obliterating its cavity (Figs. 2-63; 2-64). The chorionic tissue, however, continues to expand throughout pregnancy to accommodate the growing fetus and serves as the outer barrier between it and the maternal tissue across which physiological exchange must be maintained.

**CHORIONIC VILLI.** The **primary villi** of the chorion develop from the solid strands of trophoblast which extend into the uterine wall. The villi consist of an inner cluster of proliferating cytotrophoblast cells covered with an irregular layer of syncytiotrophoblast (Fig. 2-59). The primary villi are converted

FIG. 2-59. Primary chorionic villi. Diagrammatic. (Modified from Bryce et al., 1908.)

FIG. 2-60. Secondary or true chorionic villi. Diagrammatic. (Modified from Bryce et al., 1908.)

into the **secondary** or **true chorionic villi** by an ingrowth into each primary villus of a central core of mesoderm. Capillaries begin to differentiate within this mesodermal core and soon connect with vascular sprouts from the umbilical vessels which have grown into the chorionic mesoderm by way of the body stalk. As the chorionic villi continue to grow and ramify, the ingrowth of mesoderm and the proliferation of the umbilical vessels keep pace, establishing the structural substrate for the exchange of nutrients and metabolites between the fetal and maternal circulation (Figs. 2-60; 2-64; 2-65).

Until the end of about the second month,

the villi sprout from the entire outer surface of the chorion and are more or less uniform in size. After this time the villi nearest the body stalk of the embryo (Figs. 2-62; 2-65) grow more elaborate and complicated than the rest, becoming the fetal portion of the placenta. This is called the **chorion frondosum** (leafy chorion) and the portion of the endometrium to which it is attached is known as the **decidua basalis**. The villi in the rest or nonplacental chorion gradually atrophy and by the end of the fourth month scarcely a trace of them is left. The resulting smooth surface over this part of the chorion accounts for its name, the **chorion laeve** (Fig. 2-64).

FIG. 2-61. Diagram illustrating early formation of allantois and differentiation of body stalk.

**MATERNAL TISSUES.** Important morphologic changes occur in the endometrial wall of the uterus in preparation for the possible attachment of a developing blastocyst. It is said to enter the **progravid phase**. These changes may also be considered premenstrual because the superficial layer of the endometrial wall is lost during the menstrual period in the event that a fertilized ovum does not become implanted. If the implantation of an ovum occurs, however, the thickness and vascularity of the endometrium are greatly increased. During this **gravid phase**, the uterine glands are elongated with funnel-shaped orifices at the surface, and their deeper portions are dilated into irregular, tortuous spaces.

The trophoblastic cells of the implanted blastocyst chorion secrete a hormone called **chorionic gonadotropin**, which sustains the life of the **corpus luteum**. The resulting corpus luteum of pregnancy continues to secrete another hormone, **progesterone**. As a result of these hormonal influences, the menstrual period does not occur, and the endometrial wall of the uterus continues to develop into a favorable site for gestation. Since large amounts of chorionic gonadotropin are secreted at this time, its excess is excreted in the urine of the pregnant woman. This forms the basis of the urine pregnancy tests, one of which is the Friedman modification of the Ascheim-Zondek test. In this test 4 ml of urine are injected intravenously twice daily for two days into a

FIG. 2-62. Diagram showing later stage of allantoic development with commencing constriction of the yolk sac.

virgin, mature, female rabbit. The presence of chorionic gonadotropin, and hence a positive test for pregnancy, causes the rabbit to ovulate resulting in the presence of fresh corpora lutea or hemorrhagic corpora detectable in the ovaries of the rabbit.

The changes in the uterine wall are well advanced by the second month of pregnancy and the tissue between the uterine glands has become crowded with enlarged, glycogen-rich, connective tissue cells known as decidual cells. The endometrium consists of the following strata (Fig. 2-66): (1) the **stratum compactum**, next to the free surface, is traversed by the necks of the uterine glands and contains a rather compact layer of interglandular tissue; (2) the **stratum spongiosum** contains the tortuous and dilated glands and only a small amount of interglandular tissue; (3) the **stratum basalis**, or boundary layer next to the uterine muscular wall, contains the deepest parts of the uterine glands. At each menstrual flow and at the termination of pregnancy, the stratum compactum and stratum spongiosum are sloughed. Together these two strata of the endometrium are known as the **pars functionalis** because they are cyclically undergoing a changing histological structure in reaction to the hormonal secretions of the ovary. The stratum basalis remains relatively unchanged and serves as the source for the regenerating tissue for the functional layer.

The **decidua** (Latin *deciduus* = falling off) is the name given to the **pars functionalis** of

FIG. 2-63. Diagram showing the expansion of amnion and constriction of the yolk sac.

FIG. 2-64. Diagram illustrating a later stage in the development of the umbilical cord.

the endometrium during pregnancy. The various parts of the decidua are given special names according to their relationship to the chorion of the embryo and fetus. That part beneath the chorion frondosum is the **decidua basalis**. It is the thickest and deepest part of the endometrium between the embryo and the muscular layer of the uterus.

(Since it is also the part of the decidua involved in forming the placenta, it is sometimes called the **decidua placentalis**.) The portion of the decidua that is thin, continuous with the decidua basalis, and closes over the rest of the embryo after it has burrowed into the uterine tissue is the **decidua capsularis**. Finally, the part that lines the rest of

FIG. 2-65. Model of human embryo 1.3 mm. long. (After Eternod, Actes helv. Sci. nat. Zurich, 1896.)

**FIG. 2-66.** Diagrammatic sections of the uterine mucous membrane. A, The nonpregnant uterus. B, The pregnant uterus, showing the thickened mucous membrane and the altered condition of the uterine glands. (Kundrat and Englemann, *Stricker's Med. Jahrb.*, 1873.)

the uterus is the **decidua parietalis** or the **decidua vera** (Fig. 2-67).

During the growth of the embryo, the decidua capsularis is stretched but not broken. Gradually, by the third month the cavity of the uterus is filled, and the decidua capsularis comes into contact with the decidua parietalis (vera). By the fifth month the decidua capsularis has practically disappeared, and during the succeeding months the decidua parietalis also undergoes atrophy from the increased pressure. By this time also the glands of the stratum compactum are obliterated, and in the spongiosum they

become compressed into slit-like fissures with degenerated epithelium. In the stratum basalis, the glandular epithelium is retained.

### *The Amnion*

The human **amnion** is the inner fetal membrane that surrounds the embryo and contains the amniotic fluid in utero. It arises in the ectodermal part of the inner cell mass and lies next to the trophoblast during the second week of development. Fluid is secreted within the cluster of cells, causing the formation of the **amniotic cavity** (Figs. 2-26 to 2-28; 2-61 to 2-64). Thus, during the second and third weeks the amniotic cavity is covered by a layer of epithelial cells called **amnioblasts**, which are attached to the margins of the embryonic disc, while the floor of the cavity is formed by the columnar ectodermal cells of the disc (Fig. 2-26). As the amniotic cavity increases in size, the amnioblasts become flat and the outer surface is separated from the cytotrophoblast by a layer of extraembryonic mesoderm. About the fourth week, amniotic fluid accumulates and expands the amnion. By the end of about the second month, the amnion comes into contact with the inner wall of the chorionic sac, thereby obliterating the primitive blastocyst cavity. The amnion also grows around the body stalk and yolk sac and thus forms the covering of the umbilical cord (Figs. 2-61 to 2-64).

The amniotic fluid increases in quantity up to the sixth or seventh month of pregnancy, after which it diminishes somewhat; at the end of pregnancy it amounts to about 1 liter. The initial fluid in the amniotic cavity is probably secreted by the amnioblasts. As development continues, amniotic fluid is derived by filtration from the maternal circulation. Fetal urine also is normally found in the fluid.

The fetus is not only surrounded by the fluid but also swallows it, and the fluid not only is found in the fetal gastrointestinal tract but probably in the respiratory tract as well. The amniotic fluid allows the fetus free movement, and the buoyancy of the amniotic sac protects it from mechanical injury during the later stages of pregnancy.

### *The Yolk Sac*

The primary yolk sac probably commences development from the cluster of endodermal cells in the inner cell mass as

FIG. 2-67. Sectional plan of the gravid uterus in the third and fourth month. (After Wagner.)

early as the second week (Figs. 2-61 to 2-64). As it expands into a vesicle, two parts become distinguishable. The part lying against the embryonic disc becomes the future primitive gut of the embryo; the thinner expansion growing out into the cavity of the chorion is the more definitive yolk sac. The extraembryonic mesoderm on the outer surface of the endodermal yolk sac becomes a compact layer which differentiates quite early. During the presomite and early somite stages, the cells of this mesodermal layer proliferate rapidly, producing aggregates of cells that are known as **blood islands** and give the yolk sac a lumpy appearance (Fig.

2-68). The outermost cells of the blood islands gradually become flattened into primitive endothelium; the inner cells become separated from each other by a small amount of primitive blood plasma, and most begin to elaborate hemoglobin in their cytoplasm. The blood vessels of the yolk sac remain as the **vitelline plexus**, fed by the **vitelline** or **omphalomesenteric artery** and drained by the **vitelline** or **omphalomesenteric vein** (Fig. 2-41). In the human embryo, after it has supplied the blood cells for the beginning of circulation, the yolk sac appears to have little further function and undergoes regression (Fig. 2-69).

FIG. 2-68. Human embryo of 2.6 mm. (His, *Anatomie menschlicher Embryonen*, F. C. W. Vogel, 1880-1885.)

FIG. 2-69. Human embryo from 31 to 34 days. (His, *Anatomie menschlicher Embryonen*, F. C. W. Vogel, 1880-1885.)

At the end of the fourth week the yolk sac presents the appearance of a small pear-shaped vesicle (umbilical vesicle) and opens into the digestive tube by the long narrow **yolk stalk**. As the amnion spreads around the body stalk and over the inner surface of the chorion, the proximal part of the yolk stalk becomes enclosed in the umbilical cord. The distal part extends to the placenta and ends in the yolk sac vesicle, which lies between amnion and chorion, either on the placenta or a short distance from it (Fig. 2-67). The vesicle can be seen in the **afterbirth** as a small oval body whose diameter varies from 1 to 5 mm. As a rule the yolk stalk undergoes complete obliteration during the seventh week, but occasionally it persists within the embryo. In about 2% of adult bodies a patent omphalomesenteric duct (yolk stalk) is found as a diverticulum from the small intestine, **Meckel's diverticulum**. When present it is situated about 1 meter proximal to the ileocolic junction and may be attached by a fibrous cord to the abdominal wall at the umbilicus.

### *The Allantois*

The human **allantois** (Figs. 2-38; 2-61 to 2-65; 2-67) arises as a tubular diverticulum from the caudal wall of the yolk sac on about the 16th day of development. When the hindgut is developed the allantois retains an opening into its terminal part, the cloaca. The allantois grows out into the body stalk as a diverticulum and with it are carried the **allantoic vessels**, which eventually form the **umbilical vessels** and their branches in the chorionic villi of the placenta. In reptiles, birds, and many mammals the allantois expands into a large sac, acquires an elaborate blood supply, and plays an important metabolic role as well as serving as a reservoir for excretions. In man and other primates, however, the allantois itself remains rudimentary and of minor significance, but its blood vessels become functionally important as the umbilical vessels. The allantoic diverticulum thus extends from the fetal hindgut into the umbilical cord as a narrow canal called the **urachus**. In the fully developed infant this canal becomes obliterated. This results in the formation of a fibrous cord, the **median umbilical ligament**, which extends from the fundus of the urinary bladder to the umbilicus.

### *Body Stalk and Umbilical Cord*

The **body stalk** or **connecting stalk** develops between the embryo and the chorion, and along this stalk the embryonic blood vessels communicate with those of the chorion. Proximally, the body stalk contains the allantoic duct, whereas the umbilical vessels travel throughout its length. Subsequently the body stalk becomes a part of the **umbilical cord**.

The inner cell mass of the blastocyst during the first week is directly in contact with the trophoblast. After the development of the embryonic disc, chorionic mesoderm anchors the embryo to the inner wall of the chorion. As the embryo and the chorion grow, this mesodermal attachment becomes elongated into the body stalk (Figs. 2-62; 2-65), which extends from the posterior end of the embryo to the chorion. When the tail fold is formed, the attachment moves to the midventral region of the embryo (Figs. 2-62 to 2-64), becoming the umbilical cord.

The umbilical blood vessels grow beside the allantois into the body stalk and ramify as the chorionic vessels. These channels provide the vascular pathways to and from the embryo and the chorion. With further development of the embryo and the expansion of the amnion, the body stalk and yolk sac become enclosed in the formation of the umbilical cord. The mesoderm of the body stalk blends with that of the yolk sac and its elongated yolk stalk, being converted into a gelatinous tissue known as **Wharton's jelly**.

The umbilical cord at this stage consists of an outer covering of epithelial cells derived from the amnion and an inner mass of mesodermally derived gelatinous tissue. Within this soft tissue are the vitelline and allantoic ducts and the vitelline and umbilical (allantoic) vessels. The vitelline vessels, together with the right umbilical vein, undergo atrophy and disappear. Thus, the cord at birth contains a pair of umbilical arteries and one (the left) umbilical vein. It attains a length of about 50 cm and a diameter of about 1.5 cm (Fig. 2-70).

### **THE PLACENTA**

The **placenta** is the highly specialized organ which provides the fetus with nutrition and oxygen and removes the excretory

**FIG. 2-70.** Fetus in utero, between fifth and sixth months.

products of fetal metabolism. It is a transient organ through which fetal and maternal circulations, although closely associated functionally, remain physically separate. By means of the placenta the fetus is structurally attached to the uterine wall. It has both a fetal and a maternal portion.

The **fetal portion** of the placenta consists of the villi of the chorion frondosum. The elaborate system of villi are suspended in the intervillous space, and are bathed in maternal blood. In this manner the surface area of the trophoblastic epithelium is enormously enlarged, thereby enhancing the physiological exchange between the two circulations. Branches of the umbilical arteries enter each chorionic villus and end in capillary plexuses, which in turn are drained by tributaries of the umbilical vein. Within a villus, the endothelium of the blood vessels is surrounded by a thin layer of gelatinous mesodermal connective tissue and the trophoblast. During the first half of pregnancy the trophoblast consists of two layers: (1) the deeper stratum next to the connective tissue is the cellular **cytotrophoblast** or

Langhans' layer, and (2) the superficial layer in contact with the maternal blood of the intervillous space is the **syncytiotrophoblast**. The cells of the cytotrophoblast form a germinal layer of rapidly dividing cells, which then coalesce with the overlying syncytiotrophoblast. After about the fifth month this cell division appears to stop, and thereafter the finger-like villi are lined by only a single stratum, that of the syncytiotrophoblast.

The **maternal portion** of the placenta is formed by the decidua basalis, which lies adjacent to the chorion frondosum. Changes in the pars functionalis of the endometrial wall involve the conversion of the greater portion of the stratum compactum and the stratum spongiosum into a **basal plate** and **placental septa** (Fig. 2-71), through which the uteroplacental branches of the uterine arteries and veins pass to and from the intervillous space. The endothelial lining of these vessels ceases at the intervillous space, where the tunica media and intima become replaced by syncytiotrophoblast. Portions of the stratum compactum persist in the form of septa and extend from the basal plate through the thickness of the placenta, subdividing it into as many as 30 **lobules** or **cotyledons**. The septa project into the intervillous space and each cotyledon, considered a placental unit, contains several branching chorial trunks from which the individual free villi bathe in the surrounding pool of maternal blood (Figs. 2-60; 2-71). Fetal blood passes through the vessels of the placental villi, yet the two currents do not intermingle, being separated from each other by the delicate walls of the villi. Nevertheless, through the walls of the villi the fetal blood is able to absorb oxygen and nutritive materials from the maternal blood, and to give up its waste products to the latter. The purified blood is then returned to the body of the fetus by the umbilical vein. The term **placental barrier** has been used to refer not only to the nature of the transfer of some substances between the two circulations, but also to the blockage of others. The cellular biology of the mother-fetal relationship is also of considerable interest, especially in light of the fact that the successful fetal chorionic graft onto the maternal endometrium represents the functional union of cells of two different genotypes.

The placental attachment usually is located near the fundus of the uterus, and

TABLE 2-2. Menstrual Age with Mean Sitting Height and Weight of Fetus. (Streeter, 1921)

Menstrual age, weeks	Sitting height at end of week, mm	Increment in height		Formalin weight, grams	Increment in weight

more frequently on the posterior than on the anterior wall. It may be situated at a lower position, however, and in rare cases, its site is close to the internal os or opening into the cervix. When this occurs, the internal os may be occluded, giving rise to the condition known as **placenta previa**. In these instances the placenta may become a barrier to a normal delivery.

**SEPARATION OF THE PLACENTA.** After the child is delivered, the placenta and fetal membranes (chorion laeve and amnion) are expelled from the uterus as the **afterbirth**. Not only the decidua basalis, which underlies the chorion frondosum, but also the contiguous decidua parietalis and decidua capsularis separate from the uterine wall. The

detachment occurs through the stratum spongiosum, and necessarily causes rupture of the uterine vessels. The vessels are tightly compressed and closed, however, by the firm contraction of the uterine muscular fibers, and thus, postpartum hemorrhage normally is limited. During the postpartum period, the epithelial lining of the uterus is restored by the proliferation and extension of the epithelium, which lines the remaining portions of the uterine glands in the stratum basalis of the endometrium.

The expelled placenta is a flattened discoid mass which weighs between 450 and 600 gm and attains a diameter of 15 to 20 cm. Its average thickness is about 3 cm, but this diminishes rapidly toward the circumfer-

FIG. 2-71. Scheme of placental circulation.

ence of the disc, which is continuous with the ruptured amnion and chorion laeve. Its uterine surface is rough and uneven and is divided by a series of fissures into lobules or cotyledons. The fissures contain the remains of the endometrial septa, most of which end in irregular or pointed processes. Some septa, especially those near the edge of the placental disc, pass through its thickness and are attached to the chorion. The fetal surface of the placenta is smooth and glistening, being closely invested by the amnion. Seen through the latter, the chorion presents a mottled appearance, consisting of gray, purple, or yellowish areas. The **umbilical cord** is usually attached near the center of this surface, but may connect closer to the margin of the placental disc. In some cases the umbilical cord is inserted into the chorion laeve, peripheral to the placental disc. This so-called **velamentous insertion** can result in a more precarious placental vascular pattern.

From the attachment of the umbilical cord the larger branches of the umbilical vessels radiate under the amnion, the veins being deeper and larger than the arteries. The remains of the yolk stalk and yolk sac may also be observed beneath the amnion, close to the cord, the former as an attenuated thread, the latter as a minute sac.

## Growth of the Embryo and Fetus

**FIRST WEEK.** The human ovum is usually fertilized in the upper end of the uterine tube by sperm which have passed from the vagina, through the uterus to the oviduct. The fertilized ovum or zygote commences to divide, descends in the oviduct, and segments into about eight cells before it passes into the uterus by the end of the third day. In the uterus it continues to segment and develops into a blastocyst with a trophoblast and an inner cell mass. By the end of the first week the blastocyst has become superficially attached to the uterine mucosa.

**SECOND WEEK.** The blastocyst enlarges, loses its zona pellucida and becomes implanted more securely in the uterine wall. The trophoblast, enclosing the blastocyst cavity, develops into an actively invading outer syncytiotrophoblast and inner cytotrophoblast and forms primitive chorionic villi into which mesoderm and then blood vessels grow. From the inner cell mass develops a bilaminated embryonic disc, the amnion, and the yolk sac. The primitive streak differentiates toward the end of the second week, and mesoderm and notochord are formed.

**Fig. 2-72.** Body proportions during fetal growth and in adult life based upon average measurements and reduced to the same sitting height. With advancing growth the head, particularly its cranial part, becomes relatively smaller and the extremities in general relatively longer. The upper limb reaches its maximum prenatal length during the fifth month, but increases again in relation to the trunk height after birth. The tremendous development of the lower limb, typical for man, does not become evident until postnatal growth. The forearm grows faster than the upper arm and the leg faster than the thigh. The width between the hips increases at a more rapid rate than the width between the shoulders. In fetuses the shoulders are relatively higher above the suprasternal notch, the nipples relatively higher on the chest, and the umbilicus relatively lower on the abdominal wall than in adults. With advance in growth the breadth of the head decreases in relation to the head length, the ears become relatively larger, the eyes move closer together, the nose increases in height in relation to the face height and decreases in width in relation to the face width. (After Schultz, A. H.)

**THIRD WEEK.** During the first part of the third week the neural folds appear (Figs. 2-33; 2-35, C), the allantoic duct begins to develop, the yolk sac enlarges and blood vessels begin to form on the yolk sac and allantois and in the chorion. Before the end of the week the neural folds begin to unite (Figs. 2-35, D; 2-40) and the neurenteric canal opens. The primitive segments begin to form and the developing heart is represented by a pair of longitudinally oriented tubes. The changes during this week occur with great rapidity.

**FOURTH WEEK.** During the fourth week (Figs. 2-41; 2-45; 2-46) the neural folds close, the primitive segments increase in number, and the branchial arches appear. The connection of the yolk sac with the embryo becomes considerably narrowed, and the embryo assumes a more humanoid form. The limb buds appear and the heart increases

greatly in size, producing a prominent bulge in the branchial region.

**FIFTH WEEK.** The extensive development of the head region during the fifth week and its increase in size are due largely to the growing brain. The branchial arches undergo profound changes and partly disappear. The superficial nose, eye, and ear rudiments become prominent, and the limbs begin to show regional identity. The upper limbs develop more quickly than the lower limbs.

**SIXTH WEEK.** The curvature of the embryo's trunk is further diminished, but the cervical flexure of the head over the developing heart is more pronounced. The branchial grooves—except the first—have disappeared, and the rudiments of the fingers and toes can be recognized (Fig. 2-57).

**SEVENTH AND EIGHTH WEEKS.** The flexure of the head is gradually reduced and the

neck somewhat lengthened. The upper lip is completed and the nose is more prominent. The nostrils are directed forward, but the palate is not completely developed. The eyelids are present in the shape of folds above and below the eye, and the different parts of the auricula are distinguishable. By the end of the second month the fetus measures about 28 to 30 mm in length (Fig. 2-58).

**THIRD MONTH.** The head is extended and the neck is lengthened. The eyelids meet and fuse, remaining closed until the end of the sixth month. The limbs are well developed and nails appear on the digits. The external generative organs are so differentiated by the end of the third month that it is possible to distinguish the sex. By 13 weeks the length of the fetus is about 7 cm, but if the legs are included it measures from 9 to 10 cm.

**FOURTH MONTH.** The loop of gut which projected into the umbilical cord during the sixth week (**umbilical herniation**) is withdrawn into the fetal abdomen. The hair begins to make its appearance. There is a rapid increase in general body size so that by the end of the fourth month the fetus is from 12 to 13 cm in length, but if the legs are included it measures from 16 to 20 cm.

**FIFTH MONTH.** It is during this month that the first movements of the fetus are usually

observed. The eruption of hair on the head commences, and the **vernix caseosa**, a fatty, sebaceous material that covers the skin, begins to be deposited. By the end of this month the total length of the fetus, including the legs, is 25 to 27 cm.

**SIXTH MONTH.** The body is covered by fine hairs (*lanugo*) and the deposit of vernix caseosa is considerable. The papillae of the skin are developed, but the skin is quite wrinkled. The free border of the nail projects from the corium of the dermis. Measured from vertex to heel, the total length of the fetus at the end of the sixth month is from 30 to 32 cm.

**SEVENTH MONTH.** The pupillary membrane atrophies and the eyelids open. The testes descend with the vaginal sac of the peritoneum. From vertex to heel the total length at the end of the seventh month is 35 to 36 cm. The weight is between three and four pounds.

**EIGHTH MONTH.** The skin assumes a pink color (even the skin of fetuses of dark-

skinned races) and is now entirely coated with vernix caseosa. The lanugo begins to disappear. Subcutaneous fat has been developed to a considerable extent, and the fetus loses its wrinkles and assumes a plump appearance. The total length, i.e., from head to heel, at the end of the eighth month is about 40 cm, and fetal weight varies between 4½ and 5½ pounds.

**NINTH MONTH.** The lanugo has largely disappeared from the trunk. The umbilicus is almost in the middle of the body, and the testes are usually in the scrotum. At full term, the fetus weighs from 6½ to 8 pounds, and measures from head to heel about 50 cm.

## Surface and Topographical Anatomy

Variability is one of the few biological constants. The human body, despite fundamental similarities in structure, shows remarkable variation among individuals in its anatomy. Quite apart from specific variations that might exist as anomalies in one or another system, such as differences in vascular or neural patterns, it has been recognized that differences in general body types and stature might be categorized. The term **hypersthenic** has been used to describe the short, stout, stocky individual in contrast to **hyposthenic**, which refers to taller, more slender subjects. Naturally, the relationships of the internal organs of these differing physiques reflect the body build and become a matter for consideration in radiographic examination and interpretation.

### The Head

The shape of the cranium has also been used by physical anthropologists as a general basis for describing skull types. In the

**dolichocephalic** (long headed) skull, the maximum skull width is less than 75% of the maximum length. When the maximum width is 80% or more of the length, the term **brachycephalic** (short or broad) skull is used. **Mesaticephalic** denotes a skull in which the width is between 75% and 80% of the length.

**SCALP.** The covering of the cranial part of the head is the **scalp**, a structure composed of the following layers: (1) skin; (2) dense subcutaneous connective tissue; (3) the occipitofrontal muscle, including the galea aponeurotica; (4) subaponeurotic loose connective tissue; and (5) pericranium or periosteum of the bones (Fig. 3-1). These layers are of rather uniform thickness, so that the contours of the scalp conform largely to those of the underlying frontal, parietal, occipital, and temporal bones.

The outermost three layers of the scalp are closely adherent to each other and glide together when manipulated over the periosteum and bone, as if they were a single layer. This mobility can result in separation of the outer three layers of the scalp from the periosteum through the loose connective tissue layer as a result of accidents that cause shearing injuries.

**BONY CRANIUM.** Clearly visible landmarks are the **parietal** and **frontal eminences**, and the opening of the **external auditory meatus** of the ear. In addition, certain prominences can be identified by palpation. In the occipital region or back of the head, the **external occipital protuberance** or **inion** is a bony prominence in the midline, at the junction of the head and neck (Fig. 3-2). The **superior nuchal line** is a slight, upward curving ridge that extends laterally from the protuberance to the mastoid process of the temporal bone. Certain muscles in the neck attach to the superior nuchal line, and above it the cranium is covered only by scalp. The **mastoid process** projects downward and forward from behind the ear. Its anterior border lies immediately behind the concha of the external ear, and its rounded apex lies inferiorly at a level with the ear lobe (Fig. 3-2).

Some recognizable bony points are used in surgery and in anthropological measurements and therefore are given special names; other bony landmarks, not recognizable by observation or palpation, can be located by the use of identifiable structures as points of reference.

**FIG. 3-1.** Diagrammatic section of the scalp, the skull, and the brain. Observe the important loose connective tissue layer lying between the galea aponeurotica and the periosteum. It is through this layer that shearing accidents can separate the overlying layers of the scalp from the subjacent periosteum and bone.

**Auricular Point.** The center of the opening of the external acoustic meatus (Fig. 3-2).

**Preauricular Point.** At the root of the zygomatic arch immediately in front of the external acoustic meatus (Fig. 3-2).

**Asterion.** A point 4 cm behind and 12 mm above the auricular point. It marks the meeting of the lambdoidal, occipitomastoid, and parietomastoid sutures (Fig. 3-2).

**Zygomatic Tubercle.** A prominence on

**FIG. 3-2.** Side view of head, showing surface relations of bones.

the posterior margin of the zygomatic bone at the level of the lateral palpebral commissure of the eye (Fig. 3-2).

**Frontozygomatic Suture.** A slight depression on the posterior margin of the zygomatic bone, 1 cm above the zygomatic tubercle. It is the line of union between the zygomatic process of the frontal bone and the frontal process of the zygomatic bone (Fig. 3-2).

**Pterion.** A point 35 mm behind and 12 mm above the level of the frontozygomatic suture. It marks the point where the great wing of the sphenoid meets the sphenoidal angle of the parietal bone (Fig. 3-2).

**Inion.** The external occipital protuberance. It is palpable in the midline at the back of the skull where the posterior neck muscles attach (Figs. 3-2; 3-6).

**Lambda.** The point where the lambdoidal and sagittal sutures meet, about 6.5 cm above the inion. It marks the junction of the occipital and the two parietal bones (Figs. 3-2; 3-6).

**Bregma.** The junction site of the coronal and sagittal sutures. It can be located at the intersection of a line drawn vertically upward from the preauricular point and the midline at the top of the head (Fig. 3-2).

**Lambdoidal Suture.** This articulation between the parietal and occipital bones can be located by the upper two-thirds of a line from the mastoid process to the lambda.

**Sagittal Suture.** The midline junction of the parietal bones, between the lambda and the bregma.

**Obelion.** The point on the sagittal suture between the parietal emissary foramina; a flattened area at the top of the head.

**Coronal Suture.** This junction of the frontal and parietal bones can be approximated by a line from the bregma to the middle of the zygomatic arch.

**Glabella.** A flattened triangular area on the forehead between the two superciliary ridges.

**Nasion.** A slight depression at the root of the nose marking the frontonasal suture (Figs. 3-2; 3-6).

**Reid's base line.** This line, which is used in cranial topography (Figs. 3-2; 3-6), passes through the inferior margin of the orbit to the auricular point, and then extends back to the center of the occipital bone.

The fontanelles or soft spots in the skull of a newborn infant correspond to the above-

mentioned points and sutures as follows: (1) the **anterior fontanelle**, the largest, is at the bregma; (2) the **posterior fontanelle** is at the lambda; (3) the **lateral or sphenoidal fontanelle** is at the pterion; and (4) the **mastoid fontanelle** is at the asterion.

**FACE.** Facial features are the principal structures used for human visual recognition. Adult facial contours develop with the growth of the facial skeleton and most rapidly between the childhood years and the early post-adolescent years. Thus, the main contours of the face are governed by bony landmarks, most of which are evident to the eye but require palpation for establishment of their details.

The **superciliary ridges** are horizontal arches that extend across the forehead on each side above the eyebrow. They are part of the frontal bone above the eye, and each is marked by a depression, the supraorbital notch or foramen (Fig. 3-2).

The rim of the orbital cavity is called the **orbital margin**, and it is formed by the frontal, zygomatic, and maxillary bones.

In front of the ear, the **zygomatic arch**, formed by the temporal process of the zygomatic bone and the zygomatic processes of the temporal and frontal bones, can be palpated throughout its length (Fig. 3-2).

The **superior temporal line** is a curved ridge along the lateral aspect of the parietal bone, and it extends between the zygomatic process of the frontal bone and the region behind the ear (Fig. 3-2).

The **mandible** can be recognized and palpated throughout most of its extent. Its features include the prominence of the chin or **mental protuberance**, the **angle of the jaw**, the **alveolar portion** containing the teeth, and the **condyle**, which articulates with the temporal bone.

The **temporomandibular joint** can easily be manipulated when the mouth is opened wide; this draws the mandible forward and a depression can be felt between the condyle of the mandible and a fossa in the temporal bone, just in front of the tragus of the ear.

**MUSCLES AND SOFT PARTS.** The **masseter muscle** produces the fullness of the posterior part of the cheek, between the angle of the mandible and the zygomatic arch. Its posterior border is masked by the substance of the **parotid gland**, lying over the muscle and between it and the ear. The important duct of the parotid gland (Stensen's duct) courses

**FIG. 3-3.** Outline of side of face, showing chief surface markings as well as the superficial temporal and facial (maxillary) arteries.

transversely across the face, superficial to the masseter muscle and approximately 2 cm below the zygomatic arch (Fig. 3-3).

The anterior border of the masseter muscle may be palpated readily when the muscle is contracted by clenching the teeth; in front of it the fullness of the cheek is produced by the **buccopharyngeal fat pad** and the facial muscles.

The **temporalis muscle** occupies the temporal fossa, extending from the hollow behind the zygomatic arch to the superior temporal line (Fig. 3-5). The thick temporal fascia, covering the muscle, makes the superior border of the zygomatic arch difficult to palpate.

**ARTERIES** (Fig. 3-3). The pulsations of the **superficial temporal artery** may be felt on the surface of the temples just above the zygomatic arch in front of the ear. In older individuals its frontal branch frequently is visible making a serpentine course across the surface of the temple. The **facial artery** also may be felt as it crosses the margin of the mandible at the anterior border of the masseter muscle; it has a tortuous course from this point upward across the face on

the lateral side of the nose toward the medial angle of the eye.

**VEINS.** The **facial vein** crosses the margin of the mandible with the facial artery. It then takes a relatively straight course to the angle between the eye and nose where it is usually called the **angular vein**.

**NERVES** (Fig. 3-3). The **supraorbital nerve** emerges from the skull through the supraorbital notch (or foramen) and then courses superiorly over the superciliary ridge to innervate the anterior scalp. The **infraorbital nerve** becomes subcutaneous at the infraorbital foramen, just below the orbit. The **mental nerve** emerges from the mandible above and lateral to the mental protuberance. The **facial nerve** divides within the substance of the parotid gland, and its branches spread across the face like a fan.

**LYMPH NODES.** Usually lymph nodes are not palpable in the head, but if enlarged, the following nodes may be felt: posterior auricular, parotid, occipital, buccal, and submandibular.

**THE EYE.** The **palpebral fissure** is the elliptical opening between the two eyelids. At the extremities of the fissure, the lids are united by the **medial and lateral commissures**. At the medial commissure is a reddish elevation called the **caruncula lacrimalis**. Just lateral is a crescentic fold of conjunctiva, the **plica semilunaris**, and two small openings in the eyelids, the **puncta lacrimalia**. The **nasolacrimal duct** runs from the puncta to an opening in the inferior meatus in the lateral wall of the nasal cavity. Its direction is illustrated in Figure 3-4. The **lacrimal sac**, at the top of the duct, lies behind the medial palpebral ligament. The latter may be felt at the medial commissure if the eyelids are drawn laterally to tighten the skin. The inner surface of the eyelids is lined by the smooth and glistening epithelial layer, the **palpebral conjunctiva**. At the margin of each eyelid (**fornix**), the conjunctiva doubles back over the eyeball as the **bulbar conjunctiva**.

The colored portion of the eye is observable because the pigmented layer of the retina extends behind the **iris** and because the eyeball is covered anteriorly by a transparent sheet of tissue, the **cornea**. The central aperture in the iris is the **pupil** through which the **lens**, the **retinal vessels**, and the **optic disc** can be seen with an ophthalmoscope.

**THE EAR.** The **pinna** of the external ear is a skin-covered cartilaginous structure also

**FIG. 3-4.** Outline of bones of face showing position of the frontal and maxillary air sinuses and the line of direction of the nasolacrimal duct.

called **auricula**, and it is marked by various prominences and fossae. The external opening of the ear leads into a canal, the **external acoustic meatus**, which can be more fully exposed by drawing the **tragus** forward. The orifice is guarded by crisp hairs and contains a coating of wax, the secretion of the **ceruminous glands**. The interior of the meatus can be examined through an otoscope more easily if the auricula is drawn upward, backward, and slightly outward in order to straighten the slight curvature at the junction of the cartilaginous and bony portions of the wall. At the internal end of the meatus is the **tympanic membrane** on which are seen certain structures and markings when viewed with an otoscope. The **suprameatal triangle** (Figs. 3-5; 3-6) is an important landmark for internal structures such as the **tympanic antrum**, **facial nerve**, and **transverse sinus**.

**THE BRAIN.** The surface outline of certain brain structures of considerable practical importance can be established by external cranial landmarks and measurements (Figs. 3-6; 3-7). The **longitudinal fissure** separates

the two hemispheres at the midline and corresponds to the median line of the scalp between the nasion and the inion. The **lateral sulcus** (Sylvian) can be located by a point, termed the Sylvian point, which practically corresponds to the pterion, 3.5 cm behind and 12 mm above the level of the frontozygomatic suture. The **central sulcus** (of Rolando), which separates the cortical somatosensory centers in the precentral gyrus from the cortical motor centers of the postcentral gyrus, descends in an anterolateral direction from a projected point on the scalp 1.25 cm behind the center of the median line joining the nasion and inion. The position of the **lateral ventricle** may be shown on a ventriculogram obtained after air has been injected into it.

The branches of the **internal carotid artery** may be visualized on x-ray examination performed after injection of an opaque medium (see arteriogram, Fig. 8-31). The **middle meningeal artery** supplies the **dura mater** and courses on the inner aspect of the skull at the level of the middle of the superior border of the zygomatic arch; its anterior branch may be reached through a trephined opening slightly anterior to and below the pterion, while the posterior branch can be found through an opening about 2.5 cm above the external auditory meatus (Fig. 3-6). The **transverse dural sinus** may be approximated by a line through the asterion, and curving downward toward the mastoid process (Fig. 3-6).

**PARANASAL AIR SINUSES.** The sinuses in the head (Fig. 3-4) are mucous membrane-lined cavities within bones of the skull that vary greatly in size, shape, and position. The **frontal sinus** occupies a region in the frontal bone deep to the medial part of the superciliary ridge. The **maxillary sinus** lies in the body of the maxilla, between the orbit, nasal cavity, and upper teeth. Other sinuses are also found in the ethmoid and sphenoid bones, as well as in the mastoid portion of the temporal bone.

## The Neck

**BONES.** The relationships between the cartilaginous and bony structures in the neck can be used to practical advantage in identifying the location of soft structures that may be of clinical importance. Although

**Fig. 3-5.** Left temporal bone showing surface markings for the transverse sinus (blue) and facial nerve (yellow). Also observe the suprameatal triangle (red) lying above the external auditory meatus at the posterior end of the zygomatic process. An instrument can readily be pushed through this triangular region into the underlying tympanic antrum.

the **vertebral column** is deeply placed in the neck, certain bony landmarks can be identified by palpation.

The **transverse process of the atlas** can be felt about 1 cm below and in front of the mastoid process.

The **anterior tubercle on the transverse process of the sixth cervical vertebra** may be felt deep in the neck at the anterior border of the sternocleidomastoid muscle; it has been named the **carotid** or **Chassaignac's tubercle**, and is the point of preference for compressing the common carotid artery to stop bleeding.

The **spinous process of the seventh cervical vertebra (vertebra prominens)** can be distinguished by palpation, since it is somewhat longer than the spinous processes of the upper cervical vertebrae, and since a band of fibroelastic tissue called the **ligamentum nuchae** partially cushions the spinous processes of the upper cervical vertebrae.

The **hyoid bone** may be felt in the receding angle between the chin and anterior part

of the neck. Its vertebral level is approximately at the disc between the third and fourth cervical vertebrae. The **greater horn (greater cornu)** of the hyoid, which extends backward on a level with the angle of the mandible, can best be felt when the bone is pushed laterally toward the side to be palpated.

**LARYNX AND TRACHEA.** The **laryngeal prominence** of the **thyroid cartilage** (commonly called the Adam's apple) is visible at the midline, 1 or 2 cm below the hyoid bone (Fig. 3-8). It constitutes the anterior cartilaginous protection of the **vocal folds** of the **larynx**, and if projected posteriorly, the thyroid cartilage spans the fourth and fifth cervical vertebrae. The upper margin of the thyroid cartilage is attached to the hyoid bone by the **thyrohyoid membrane**, and its lower margin to the **cricoid cartilage** by the **cricothyroid ligament**. The level of the vocal folds corresponds to the middle of the anterior border of the thyroid cartilage.

The **cricoid cartilage** lies at the level of the sixth cervical vertebra (Fig. 3-8). Below it the

**Fig. 3-6.** Relations of the brain and middle meningeal artery to the surface of the skull. 1, Nasion. 2, Inion. 3, Lambda. 4, Lateral cerebral fissure. 5, Central sulcus. AA, Reid's base line. B, Point for trephining the anterior branch of the middle meningeal artery. C, Suprameatal triangle. D, Sigmoid bend of the transverse sinus. Outline of cerebral hemisphere indicated in blue; course of middle meningeal artery in red.

trachea can be felt, but only in thin subjects can the individual cartilaginous rings be distinguished. As a rule there are seven or eight rings above the **jugular notch** of the sternum, and the isthmus of the **thyroid gland** covers the second, third, and fourth rings. The trachea measures about 10 cm in length before it bifurcates into the primary bronchi. Of these 10 cm, 5 extend in the neck above the suprasternal notch, while 5 extend in the thorax below the suprasternal notch.

**MUSCLES.** The **sternocleidomastoid muscle** is the most prominent muscle in the neck. Its entire extent, from the mastoid process to the sternal and clavicular heads (Fig. 3-8), is clearly visible in most persons. The **trapezius** muscle forms the superior curvature of the shoulder, sloping upward toward the posterior neck and back of the head. The **platysma** is a thin superficial sheet of muscle overlying the anterior neck. It wrinkles the skin of the neck when contracted and can be detected when thrown into prominence by expressions of horror or sudden and intense muscular efforts requiring deep inspiration.

**TRIANGLES OF THE NECK.** The lack of prominent topographical features and the large number of important nerves and blood vessels contained within the neck have made it customary to subdivide this region into smaller areas. These areas, triangular in shape and related to some of the more superficial muscles, are known as the triangles of the neck. The side of the neck presents a quadrangular shape limited above by the lower border of the **mandible**, below by the **clavicle**, in front by the **midline**, and behind by the **anterior border of the trapezius muscle**. This is subdivided obliquely into two large triangles by the **sternocleidomastoid muscle**. The triangle in front of this muscle is called the **anterior triangle**; the one behind it, the **posterior triangle**.

**Anterior Triangle.** The anterior triangle is bounded anteriorly by the **midline**, and posteriorly by the anterior border of the **sternocleidomastoid muscle**; its apex is below at the sternum, and its base is formed by the lower margin of the **body of the mandible** and an extension of this line to the mastoid

**FIG. 3-7.** Drawing of a cast to illustrate the relationships of the brain with the overlying skull. Note that the convolutions of the cerebral cortex can be described as comprising the frontal (blue), temporal (green), parietal (yellow), and occipital (red) lobes.

process. This larger triangle is subdivided, by the **digastric muscle** above and the superior belly of the **omohyoid muscle** below, into four smaller triangles: **muscular**,

**carotid**, **submandibular**, and **submental** (Fig. 3-9).

The **muscular triangle** is bounded in front by the midline of the neck; behind by the

**FIG. 3-8.** Anterior and lateral view of head and neck showing surface markings.

**FIG. 3-9.** The triangles of the neck. The sternocleidomastoid muscle divides the anterolateral aspect of the neck into large anterior and posterior triangles (not labeled). The posterior triangle is further subdivided by the inferior belly of the omohyoid into the occipital and omoclavicular triangles. The anterior triangle is crossed by the superior belly of the omohyoid, thereby forming the carotid and muscular triangles. Above the hyoid bone are located the submandibular and submental triangles.

superior belly of the omohyoid above, and the anterior margin of the lower part of the sternocleidomastoid below. In this triangle, under cover of the skin, subcutaneous fascia, platysma, and deep fascia, are the **sternohyoid** and **sternothyroid** muscles, the **isthmus of the thyroid gland**, the **larynx**, and the **trachea**. Although not within the triangle as defined above, the following structures can be approached surgically through the triangle by displacing the sternocleidomastoid laterally: the lower part of the common carotid artery in the carotid sheath with the internal jugular vein and vagus nerve, the ansa cervicalis, the sympathetic trunk, recurrent laryngeal nerve, and the esophagus.

The **carotid triangle** is bounded *behind* by the sternocleidomastoid muscle; *below* by the superior belly of the omohyoid muscle; and *above*, by the stylohyoid muscle and the posterior belly of the digastric muscle (Fig. 3-9). It is covered by the skin, subcutaneous fascia, platysma, and deep fascia, layers that contain the ramifications of the cutaneous cervical nerves and the cervical branch of the facial nerve. The floor or deepest part of the triangle is formed by the thyrohyoid, hyoglossus, and middle and inferior pharyngeal constrictor muscles. In the triangle, especially if it is enlarged by displacing the sternocleidomastoid backward, is the upper part of the **common carotid artery**, which

bifurcates at the level of the upper border of the thyroid cartilage into the **internal and external carotid arteries**. The internal carotid artery lies posterior and somewhat lateral to the external carotid and gives off no branches in the neck. The branches of the external carotid artery in the carotid triangle are the superior thyroid, the lingual, the facial, the occipital, and the ascending pharyngeal. Enclosed with the arteries in a fascial membrane, the **carotid sheath**, are the **internal jugular vein** and the **vagus nerve**. The tributaries of the vein correspond with the branches of the external carotid: superior thyroid, lingual, facial, ascending pharyngeal, and sometimes the occipital. Superficial to the carotid sheath is the **ansa cervicalis**, and deep to it or embedded in its substance is the **sympathetic trunk**. The **hypoglossal nerve** crosses both the internal and external carotids in the upper part of the triangle, curving around the origin of the occipital artery. Between the external carotid and the pharynx, just below the hyoid bone, is the internal branch of the **superior laryngeal nerve**; the external branch is slightly lower. The **accessory nerve** may cross the uppermost corner of the triangle.

Between the hyoid bone and the superior border of the thyroid cartilage at the level of the carotid bifurcation is a slight dilatation of the common carotid artery, the **carotid sinus**. This is an organ of sensory receptors, innervated by the glossopharyngeal nerve, which is capable of sensing blood pressure changes. Also located at the carotid bifurcation is the **carotid body**. Innervated by fibers of both the glossopharyngeal and vagus nerves, the carotid body contains chemoreceptors capable of responding to undue changes in carbon dioxide or oxygen in the blood.

The **submandibular triangle**, located immediately below the body of the mandible, is bounded *above* by the lower border of the body of the mandible and an extension of this line to the mastoid process; *below* by the posterior belly of the digastric muscle and the stylohyoid muscle; and *in front* by the anterior belly of the digastric muscle (Fig. 3-9). It is covered by skin, subcutaneous fascia, platysma, and deep fascia, within which ramify motor branches of the facial nerve (to platysma) and sensory filaments from the cervical cutaneous nerves. The muscular floor of the triangle is formed by the mylohyoid and hyoglossus muscles. The styloman-

dibular ligament at the angle of the mandible divides the triangular area into an anterior and a posterior part. The anterior part contains the **submandibular gland**, which is crossed by the anterior facial vein and facial artery. Deep to the gland are the submental artery and the mylohyoid artery and nerve. The posterior part of this triangle is largely occupied by the **parotid gland**. By displacing the muscles slightly, certain deeper structures may be included. In its superior course, the external carotid artery is crossed by the facial nerve. The vessel then becomes embedded within the parotid gland, and gives off its posterior auricular, superficial temporal, and maxillary branches. At this level the internal carotid artery, internal jugular vein, and vagus nerve are more deeply situated in the neck and are separated from the external carotid by the styloglossus and stylopharyngeus muscles and the glossopharyngeal nerve.

The **submental triangle** is bounded posteriorly by the anterior belly of the digastric muscle, *anteriorly* by the midline, and *inferiorly* by the body of the hyoid bone (Fig. 3-9). Its floor is formed by the **mylohyoid muscle**, and the triangle contains several lymph nodes which drain the chin and lower lip along with the anterior tongue and floor of the mouth. Several smaller veins drain into the anterior jugular vein.

**Posterior Triangle.** The posterior triangle is bounded in front by the **sternocleidomastoid muscle** and *behind* by the anterior margin of the **trapezius**; its base is the middle third of the **clavicle**, and its apex is at the occipital bone. About 2.5 cm above the clavicle, it is crossed obliquely by the inferior belly of the omohyoid, dividing it into an upper or **occipital** and a lower or **omoclavicular** (supraclavicular or subclavian) triangle.

The **occipital triangle** (Fig. 3-9) is bounded *in front* by the sternocleidomastoid; *behind* by the trapezius; and *below* by the omohyoid. Its muscular floor is formed by the splenius capitis, the levator scapulae, and the scalenus medius and posterior, and it is covered by the skin, subcutaneous fascia, superficial fascia, and deep fascia. About midway along the posterior border of the sternocleidomastoid muscle, the **spinal accessory nerve** emerges from beneath the muscle to cross the triangle obliquely in an inferolateral direction on its path to innervate the trapezius muscle. Somewhat lower, the cervical cuta-

neous and supraclavicular nerves also emerge from under the posterior border of the sternocleidomastoid. In the lowest part of the triangle, the transverse cervical vessels along with the uppermost part of the brachial plexus may be seen.

The **omoclavicular triangle** (Fig. 3-9) is bounded *above* by the inferior belly of the omohyoid muscle; *below* by the clavicle; and *in front* by the sternocleidomastoid muscle. Its floor is formed by the first rib and the first digitation of the serratus anterior muscle. To some extent the size of the omoclavicular triangle depends on the breadth of the attachment of the sternocleidomastoid and trapezius to the clavicle and the position of the omohyoid. Some of the structures listed below might be reached by displacement of the muscles, since the triangle is increased in size by drawing the shoulder downward to lower the clavicle. The triangular area is covered by skin, subcutaneous fascia, platysma, and the deep fascia that contains the supraclavicular nerves. Medially, within the triangle, the third part of the **subclavian artery** emerges from behind the scalenus anterior and curves down behind the clavicle. Sometimes the arch of the artery rises by as much as 4 cm above the clavicle, and this is the most commonly chosen place for ligature. The **subclavian vein** usually rests behind the clavicle, but may be found partially within the triangle. The suprascapular vessels cross the lower part and the superficial cervical vessels the upper part of the triangle. The **external jugular vein** enters the anterior part of the triangle from its position on the surface of the sternocleidomastoid muscle and empties into the subclavian vein; its tributaries, the transverse scapular and transverse cervical veins, form a plexus superficial to the subclavian artery. The **brachial plexus** of nerves crosses the lateral part of the triangle, coming into close relationship with the subclavian artery in its descent behind the clavicle to the axilla. A portion of the plexus courses above the subclavian artery, while another part courses behind the vessel.

**ARTERIES.** The position of the **common** and **external carotid arteries** can be approximated by a line drawn from the upper part of the sternal end of the clavicle to a point midway between the tip of the mastoid process and the angle of the mandible. Above the carotid bifurcation at the upper border of

the thyroid cartilage, this line overlies both internal and external carotids until the latter arches backward slightly toward the external acoustic meatus. The *main branches* of the *external carotid* originate near the tip of the greater horn of the hyoid bone. The arching course of the *subclavian artery* upward from the sternoclavicular joint to the middle of the clavicle can be observed in Figure 3-10.

**VEINS.** The **internal jugular vein** is parallel and slightly lateral to the internal carotid artery. The **external jugular** runs from the angle of the mandible to the middle of the clavicle.

**NERVES.** The **facial nerve** emerges from the stylomastoid foramen about 2.5 cm deep to the surface of the skin, opposite the anterior border of the mastoid process. The **accessory nerve** courses quite superficially as it crosses the posterior triangle. Emerging from under the posterior border of the sternocleidomastoid muscle, it achieves the anterior border of the trapezius muscle. Also appearing from under the posterior border of the sternocleidomastoid in this same region are the following **cutaneous nerves**: the *lesser occipital*, the *greater auricular*, the *anterior cervical cutaneous*, and the *supraclavicular nerves* (Fig. 3-10). The **phrenic nerve** is formed from cervical roots at the level of the middle of the thyroid cartilage. It then passes inferiorly to the thorax beneath and about half way between the two borders of the sternocleidomastoid. In its course it lies in front of the scalenus anterior muscle. The upper part of the **brachial plexus** can be located by a line drawn from the cricoid cartilage to the middle of the clavicle. The **vagus nerve** and **sympathetic trunk** run parallel and deep to the internal carotid artery.

**LYMPH NODES.** Lymph nodes may be felt between the ramus of the mandible and the sternocleidomastoid muscle, along the course of the internal jugular vein, and along both the anterior and posterior borders of this muscle.

## The Back

**BONES.** The furrow down the middle of the back lies over the tips of the *spinous processes of the vertebrae*. The upper cervical vertebrae cannot be felt, but the seventh, or **vertebra prominens**, can be distinguished easily and lies just above the even more

**Fig. 3-10.** The anterolateral aspect of the neck showing the course of principal arteries, cutaneous nerves, and the spinal accessory nerve.

prominent *first thoracic*. Other vertebral spinous processes can be identified by counting from these. The posterior surface of the **scapula** is marked by a prominent obliquely crossing plate of bone called the *spine of the scapula*. This lies on a level with the third thoracic spinous process, while the inferior angle of the scapula is at the level of the seventh thoracic spinous process. The highest point of the **crest of the ilium** is on a level with the fourth lumbar spinous process (Fig. 3-11), and the **posterior superior iliac spine** is level with that of the second sacral.

**SPINAL CORD.** The **spinal cord** extends downward to the level of the spinous process of the second lumbar vertebra in the adult body (Fig. 3-12), but as far as the fourth in an infant. The **subarachnoid space**, containing the spinal fluid, extends downward to the third sacral vertebra. Because the sub-

stance of the spinal cord ends at the second lumbar level, the dural and arachnoid sacs below that level containing the lumbar and sacral nerve roots (**cauda equina**) surrounded by spinal fluid are used to advantage for the induction of spinal anesthesia. Injections of anesthetics, for example, through the fourth lumbar interspace may be performed in the adult without much danger of striking the spinal cord.

**MUSCLES.** The **muscles** of the back are large and their surface contours usually can be identified with ease in a living subject (Fig. 3-33).

## The Thorax

Several prominent muscles that extend either into the scapula or into the upper extremity cover the bony thoracic cage. Anteri-

**Fig. 3-11.** Surface anatomy of the back.

orly, these include the pectoralis major and the serratus anterior, along with the upper portions of the abdominal muscles (Figs. 3-13; 3-18). Posteriorly the superficial back muscles (trapezius and latissimus dorsi) overlie the deeper muscles of the shoulder and back (Fig. 3-11). Each **axilla**, or hollow of the armpit (Fig. 3-37), is limited by two fleshy folds: the **anterior axillary fold** is the prominence caused by the pectoralis major, while the **posterior axillary fold** is the prominence of the latissimus dorsi. A **triangle of auscul-**

**tation** can be identified on the posterior thoracic wall bounded *above* by the trapezius, *below* by the latissimus dorsi, and *laterally* by the medial border of the scapula. Drawing the scapula forward by folding the arms across the chest will reveal the sixth and seventh ribs subcutaneously at this site, and allow for auscultation of the thorax.

The size of the **breast** or **mamma** is subject to great variation. In most adult nulliparous females it extends vertically from the second to the sixth ribs, and transversely from the

**Fig. 3-12.** Diagram showing the relationships of the spinal cord to the dorsal surface of the trunk. Observe that the substance of the spinal cord reaches to the upper lumbar levels of the spinal column. Below this the spinal canal contains spinal nerves and it can be punctured to achieve the cerebrospinal fluid compartment.

sternum to the midaxillary line. In males the **mammary papilla** or **nipple** is situated in the fourth intercostal space (Fig. 3-14), while in females the position of the nipple is so variable that it is much less useful as a surface landmark for intrathoracic structures.

**BONY LANDMARKS.** The **sternum**, **ribs**, **scapula**, and **clavicle** can be seen in many individuals and can be felt in all but the very muscular or obese subjects. The upper border of the sternum is marked by the **jugular** (or **suprasternal**) **notch**, between the sternal heads of the two sternocleidomastoid muscles (Fig. 3-8). In the midline the sternum is subcutaneous, leaving the sternal furrow between the origins of the two pectoralis major muscles. The junction between the two parts of the sternum, the **manubrium** above and the **body** (or **gladiolus**) below, is marked by a well-defined transverse ridge

about 5 cm below the jugular notch. This ridge, called the **sternal angle** or **angle of Louis**, is opposite the sternochondral junction of the second rib (Fig. 3-18). At the lower end of the body of the sternum is the **infra-sternal notch** in the midline between the sternal attachments of the seventh costal cartilages of both sides. In the triangular depression, called the **epigastric fossa**, below the notch, the **xiphoid process** of the sternum can be felt.

Additional bony relationships of these sternal structures can be identified with the vertebrae of the spinal column. If projected posteriorly, the **jugular notch** lies at the lower level of the second thoracic vertebra, the **sternal angle** is at the level of the lower part of the fourth thoracic vertebra, and the junction between the xiphoid process and the body of the sternum (**xiphisternal junction**) projects backward to the body of the tenth thoracic vertebra.

The **ribs** can usually be felt at the sternochondral junction in front, on the sides of the thorax, and in back as far as their angles, although they are mostly covered by muscles. The first rib is difficult to palpate because it is deeply situated and partly hidden by the clavicle. The **second rib** is the one most reliably identified because of its attachment at the sternal angle, and from this point the other ribs can be counted. The lower boundary of the thorax is formed by the xiphoid process, the cartilages of the seventh, eighth, ninth, and tenth ribs, and the ends of the eleventh and twelfth cartilages (Figs. 3-17; 3-19).

**LINES FOR ORIENTATION** (Fig. 3-21). Certain arbitrarily accepted lines offer some value for clinical orientation and descriptive purposes. The **midsternal line** is the midline of the body over the sternum. The **midclavicular** or **mammary line** is a vertical line, parallel with the midsternal, through a point midway between the center of the jugular notch and the tip of the acromion or point of the shoulder. The **lateral sternal line** is a vertical line along the sternal margin over the sternochondral junctions. The **anterior** and **posterior axillary lines** are vertical lines drawn along the corresponding axillary folds, while the **midaxillary line**, halfway between them, passes through the apex of the axilla. On the back, the **scapular line** is drawn vertically through the inferior angle of the scapula (Fig. 3-11).

Fig. 3-13. Surface anatomy of left side.

**THE LUNGS** (Figs. 3-14, 3-15). The **apex of the lung** lies behind the medial third of the clavicle and extends superiorly into the neck from 1 to 5 cm, but usually about 2.5 cm. The **anterior border** of the right lung approaches the midsternal line, that of the left does likewise as far as the fourth costal cartilage, where it deviates laterally because of the **cardiac notch**. The **inferior border** of each lung at expiration follows a curving line downward from the sixth sternocostal junction anteriorly to the spinous process of the

tenth thoracic vertebra posteriorly. This line crosses the midclavicular line at the sixth and the midaxillary line at the eighth rib. The **posterior border** of each lung is parallel with the midline (Fig. 3-15), 2 to 3 cm from it, and extends from the spinous process of the seventh cervical vertebra to that of the tenth thoracic vertebra.

The reflections of the **pleura** correspond in general with the surface of the lungs, but are more extensive. At expiration the **parietal pleurae** of the two sides of the thorax ap-

**FIG. 3-14.** Anterior view of the thorax to show the position of the heart in relationship to the ribs, sternum, and diaphragm, and the position of the heart valves. (From Crouch, J.E.; *Functional Human Anatomy*. Lea & Febiger, 1978.)

**FIG. 3-15.** Left lateral view of thorax showing surface markings for bones, lungs (purple), pleura (blue), and spleen (green).

proximate each other in the midline anteriorly, opposite the second or fourth costal cartilages. The most medial 1 or 2 cm of the pleural cavity anteriorly are unoccupied by lung, but consist of a slit-like cavity forming a potential space between the two layers of pleura known as the **costomediastinal sinus**. The inferior limit of the pleura extends 2 to 5 cm below that of the lung at expiration, leaving the **phrenicocostal sinus** also unoccupied by lung. This site is frequently used for the introduction of a needle into the pleural cavity in order to aspirate fluid from the chest. The inferior limit of the thorax is the **diaphragm** (Fig. 3-16), and its attachment to the thoracic wall along the costal margin is 2 to 3 cm below the inferior limit of the pleura.

**THE HEART.** The apex of the heart is directed inferolaterally in the **middle mediastinum** of the thorax, and its pulsation may be felt in the fifth intercostal space just below the nipple or about 9 cm to the left of the midsternal line. A projection of the heart outline on the anterior chest wall can be approximated in the following manner: the **superior margin** is marked by a horizontal line at the third sternochondral attachment;

**FIG. 3-16.** The heart and cardiac valves projected on the anterior chest wall, showing their relationship to the ribs, sternum, and diaphragm. (Eycleshymer and Jones, 1925.)

the **right margin** corresponds to a vertical line drawn 2.5 cm lateral to the right sternal margin; the **inferior** or **diaphragmatic margin** is marked by a line sloping slightly downward and to the left at the xiphisternal junction; and the **left margin** angles upward from the apex (located 9 cm to the left in the fifth intercostal space) to the second intercostal space 2.5 cm from the left sternal margin. The superior margin is also the **base of the heart** and marks the beginning of the great vessels. The position of the chambers, sulci, and valves is shown in Figure 3-16.

It should be noted that a portion of the heart is not covered by lung and lies directly beneath the bony thorax (Figs. 3-14; 3-17), while the remainder is overlapped by lung tissue. Upon percussion of the chest over that region of the heart not covered by lung, a less resonant tone is heard and this zone has been called the area of **superficial car-**

**diac dullness.** The chest area over the remainder of the heart covered by lung is called the area of **deep cardiac dullness.** A circle 5 cm in diameter around a point midway between the male nipple (fourth inter-space) and the end of the sternum usually outlines the area of superficial dullness.

The **internal thoracic vessels** course vertically 1 cm lateral to the sternal margin and extend inferiorly from the subclavian vessels above the first rib to the sixth cartilage. The **intercostal vessels** and **nerves** generally lie along the inferior borders of the ribs in their intercostal spaces in the anterior wall and tend to lie deep to the ribs posteriorly.

## The Abdomen

**MUSCLES.** The contours of the abdominal wall are established largely by the muscles, with modifications brought about by the

**Fig. 3-17.** Thoracic and abdominal viscera shown in their normal relationship to the skeleton. Anterior view. (Eycleshymer and Jones, 1925.)

accumulation of adipose tissue in the subcutaneous layers. A groove in the midline called the **linea alba** separates the medial margin of the **rectus abdominis** of one side from that of the other. It extends from the infrasternal notch above to the pubic symphysis below, and its fibrous structure is formed by the decussating fibers of the apo-

neuroses of the underlying flat abdominal muscles (Figs. 3-18; 3-28). The **umbilicus** (or navel) interrupts the linea alba about midway along its extent. This depressed scar is the site of attachment of the umbilical cord of the fetus. In most individuals it lies at the level of the intervertebral disc between the third and fourth lumbar vertebrae. The **linea**

**FIG. 3-18.** Anterior view of the body showing surface contours of the neck, thorax, upper extremity, and abdomen.

**semilunaris** is a curved, vertically oriented groove located on both sides of the anterior abdominal wall at the lateral margin of the rectus abdominis muscles (Fig. 3-28). It is not as clearly marked as the linea alba except in muscular subjects, but becomes more evident when the rectus abdominis is in action. At the level of the umbilicus, the linea semilunaris lies about 7 cm from the midline, curving medially as it nears the pubis.

Lateral to the rectus, the **external oblique**

**muscle of the abdomen** (Fig. 3-18) becomes the most superficial muscle; it interdigitates with the **serratus anterior** above, and posteriorly it is partly overlapped by the **latissimus dorsi**. A separation between the external oblique and the latissimus at their attachment to the crest of the ilium is known as the **lumbar triangle** (of Petit). This triangle is bounded *medially* by the latissimus dorsi, *laterally* by the external oblique, and *inferiorly* by the crest of the ilium. The floor of the

triangle is formed by the internal oblique muscle.

At the lower border of the external oblique, the **inguinal ligament** lies in the floor of the groove of the groin. The ligament is formed by the thickened inferior border of the aponeurosis of the external oblique. The surface of the rectus abdominis muscle, especially in a muscular subject, has three transverse furrows caused by the **tendinous inscriptions**: one is a little below the xiphoid process, one is at the umbilicus, and the third is between these two.

The **superficial inguinal ring** (Fig. 3-28), an opening in the aponeurosis of the external oblique, is situated 1 cm above and lateral to the pubic tubercle; the **deep inguinal ring** lies 1 to 2 cm above the middle of the inguinal ligament. The position of the **inguinal canal**, which contains the **spermatic cord** in the male and the **round ligament of the uterus** in the female, is indicated by a line joining these two rings.

**BONY LANDMARKS.** Bony landmarks that help define the abdomen include: the lower border of the thorax above, which has already been described, and the bony pelvis below (Figs. 3-19; 3-20). The **crest of the ilium** may be identified by the prominent **tubercle** on its outer lip which can be seen or palpated. The **anterior superior iliac spine** may be felt in the groin at the lateral end of the inguinal ligament (Figs. 3-17; 3-18), and the **pubic tubercle** may be felt at the medial end of the ligament, a point which may also be identified as the inferior attachment of the rectus abdominis muscle.

**ABDOMINAL PLANES AND REGIONS.** For convenience of description and reference, the abdomen can be divided into nine regions by four imaginary planes, two horizontal and two sagittal (Fig. 3-21). Indicated by lines on the surface of the abdominal wall, the two transverse lines are (1) an upper transverse, the **transpyloric**, situated halfway between the jugular notch and the upper border of the symphysis pubis; this line cuts through the pylorus of the stomach, the tips of the ninth costal cartilages, and the lower border of the first lumbar vertebra; (2) a lower transverse line termed the **trans-tubercular**, which passes across the iliac tubercles and cuts the body of the fifth lumbar vertebra. By means of these horizontal planes the abdomen is divided into three zones. These are further subdivided into

three regions each by two sagittal planes, which are indicated on the surface by **right** and **left lateral lines** drawn vertically through points halfway between the anterior superior iliac spines and the midline. The middle region of the upper zone is called the **epigastric**, and the two lateral regions the **right** and **left hypochondriac**. The central region of the middle zone is the **umbilical**, and the two lateral regions the **right** and **left lumbar**. The middle region of the lower zone is the **hypogastric** or **pubic**, and the lateral are the **right** and **left iliac** or **inguinal**.

Another more simplified but quite useful subdivision of the abdomen consists of two planes at right angles to each other, one corresponding to the midsagittal plane of the body, the other to a transverse plane through the umbilicus. The resulting four portions are known as **quadrants**, the upper and lower, right and left.

**VISCERA.** Under normal conditions the various portions of the digestive tube cannot be identified by simple palpation. The greater part of the liver lies under cover of the ribs and cartilages, especially in the supine position, but during a deep inspiration it may be pushed out below the costal margin on the right side and felt (Figs. 3-17; 3-22). Other viscera can only be palpated in emaciated subjects with lax abdominal walls, or if they are the seat of disease or tumors.

**Stomach** (Figs. 3-17; 3-22; 3-23). The shape of the stomach changes throughout the day and is affected by the particular phase of digestion, by the state of the surrounding viscera, and by the amount and character of its contents. Its position also varies with that of the body, so that it is impossible to indicate its position on the body surface with any degree of accuracy. The reference points and measurements given below refer to a moderately filled stomach with the body in the supine position.

The **cardiac orifice** lies deep to the seventh left costal cartilage about 2.5 cm from the left sternal border; it corresponds to the level of the tenth thoracic vertebra. The **pyloric orifice** is along the transpyloric line about 1 cm to the right of the midline, or alternately 5 cm below the seventh right sternocostal articulation; it is at the level of the first lumbar vertebra.

**Duodenum** (Fig. 3-24). The duodenum consists of four parts, **superior**, **descending**, **horizontal**, and **ascending**. It is approxi-

**FIG. 3-19.** Thoracic and abdominal viscera shown in their normal relationship to the skeleton. Posterior view. (Eycleshymer and Jones, 1925.)

mately 25 cm in length, shaped in the form of a "C," and is the commencement of the small intestine. The superior part passes transversely to the right and somewhat posteriorly. It extends from the pylorus nearly to the right lateral line. The descending part, situated medial to the right lateral line,

courses inferiorly from the transpyloric line (L1) to a point midway between the transpyloric and transtubercular lines (between L3 and L4). The horizontal part runs transversely, but with a slight upward slope from the end of the descending part to the left of the midline. The ascending part is

**Fig. 3-20.** Thoracic and abdominal viscera shown in their normal relationship to the skeleton, from the left side. (Eycleshymer and Jones, 1925.)

vertical, reaches the transpyloric line, and ends at the duodenojejunal flexure, about 2.5 cm to the left of the midline.

**Jejunum and Ileum.** The coils of small intestine, comprising the **jejunum** and **ileum**, occupy most of the abdomen. Usually the greater part of the jejunum is situated on the left side of the abdomen, while the coils of the ileum are located on the right side and

partially within the pelvis. The small intestine terminates at the **ileocolic junction**, which is slightly below and medial to the intersection of the right lateral and trans-tubercular lines (Fig. 3-21).

**Cecum and Vermiform Appendix.** The **cecum** is in the right iliac and hypogastric regions. Its position varies with its degree of distention, but a line drawn from the right

**FIG. 3-21.** Surface lines on the anterior aspect of the thorax and abdomen. Observe the arbitrary subdivision of the abdomen into nine zones by two transverse planes (transpyloric and transtuberular) and two vertical planes (right and left lateral lines).

anterior superior iliac spine to the upper margin of the symphysis pubis will mark approximately the middle of its lower border. The position of the base of the **appendix** is indicated by a point on the lateral line, level with the anterior superior iliac spine (Fig. 3-22).

**Ascending Colon** (Figs. 3-17; 3-19; 3-22; 3-26). The ascending colon, in contact with the posterior wall of the abdomen, passes upward from the right iliac region through the right lumbar region, lateral to the right lateral line. It bends abruptly at the **right colic flexure**, which is situated at the inter-

section of the subcostal and right lateral lines. The right costal margin, the right lobe of the liver, and the gallbladder overlie the right colic flexure.

**Transverse Colon** (Figs. 3-17; 3-20; 3-22; 3-23). The transverse colon is the most mobile part of the large intestine and it crosses the abdomen in the epigastric region. Its lower border is located on a level slightly above the umbilicus, while its upper border lies just below the greater curvature of the stomach (Fig. 3-17).

**Descending Colon** (Figs. 3-19; 3-20; 3-26). Under cover of the left costal margin and in

**Fig. 3-22.** Anterior aspect of abdomen showing the surface projections for the liver, stomach, and large intestine.

relationship to the spleen, the transverse colon turns sharply downward and becomes the descending colon at the **left colic flexure**. This flexure is situated approximately at the intersection of the left lateral and transpyloric lines. The descending colon courses inferiorly through the left lumbar region, lateral to the left lateral line, as far as the iliac crest.

**Sigmoid Colon** (Figs. 3-17; 3-20). The iliac and pelvic portions of the large intestine form the **sigmoid colon**. The iliac portion is contained in the left iliac fossa, and continues as the pelvic colon at the left lateral line. The sigmoid colon is freely moveable since it has a mesentery, and it becomes the **rectum** anterior to the sacrum in the midline (Figs. 3-19; 3-20; 3-23; 3-27).

**Liver** (Fig. 3-17; 3-22). The **liver** is located in the right hypochondrium, extending across the midline toward the left into the upper part of the epigastric region. Although the liver moves up and down with respiration, the upper limit of its right lobe, in the midline, is at the level of the junction between the body of the sternum and the xiph-

oid process. On the right side the superior border of the liver carries upward as far as the fifth costal cartilage in the midclavicular line. On the left side the liver extends across the midline as far as 7 or 8 cm. Its upper margin is somewhat lower than on the right, reaching the sixth costal cartilage. The inferior extent of the liver can be indicated by a line drawn 1 cm below the lower margin of the thorax on the right side as far as the ninth costal cartilage, then obliquely upward to the eighth left costal cartilage, crossing the midline just above the transpyloric plane. Finally, with a slight left convexity, the inferior border reaches the end of the line, indicating the upper limit at about the fifth left interspace.

**Gallbladder.** The **gallbladder** is attached to the inferior (visceral) surface of the liver (Figs. 3-17; 3-23). Its **fundus** is directed inferiorly and projects just beyond the lower border of the right lobe of the liver at the ninth right costal cartilage close to the lateral margin of the rectus abdominis.

**Pancreas** (Fig. 3-24). The **pancreas** lies in front of the second lumbar vertebra. Its head

**FIG. 3-23.** Thoracic and abdominal viscera shown in their normal relationship to the skeleton from the right side. (Eycleshymer and Jones, 1925.)

occupies the curve of the duodenum and is therefore indicated by the same lines as that viscus; its *neck* corresponds to the pylorus. Its *body* extends along the transpyloric line, the bulk of it lying above this line; the *tail* is in the left hypochondriac region, extending slightly to the left of the lateral line and above the transpyloric line.

**Spleen** (Figs. 3-15; 3-17; 3-19; 3-20; 3-25). The long axis of the spleen corresponds to that of the tenth rib on the left side. It is situated between the upper border of the ninth and the lower border of the eleventh ribs. It is separated from the ribs by the diaphragm. Its medial end is about 4 cm to the left of the midline of the back. Its lateral extent is the

**Fig. 3-24.** Front of abdomen, showing surface projections for duodenum, pancreas, and kidneys. AA', Plane through the xiphisternal junction. BB', Plane midway between AA' and transpyloric plane. CC', Plane midway between transpyloric and transtuberular planes. The vertical lines are the left and right lateral lines between which is the midline.

left midaxillary line at the ninth intercostal space.

Lying obliquely in the left hypochondrium, the superior border of the spleen at times can extend more medially into the epigastrium. The inferior pole of the spleen is generally described as extending to the level of the first lumbar vertebra in the cadaver; however, in the erect, living person, it usually extends significantly lower, to the third lumbar vertebra.

**Fig. 3-25.** Back of lumbar region, showing surface projections for kidneys, ureters, and spleen. The lower portions of the lung and pleura are shown on the right side.

**Kidneys** (Figs. 3-19; 3-20; 3-23; 3-24 to 3-27). The **kidneys** are located in the posterior abdomen on each side of the spinal column. The right kidney usually lies about 1 cm lower than the left because of the presence of the liver on the right side, but for practical purposes similar surface markings may be taken for each.

Projected anteriorly, the upper pole of each kidney lies along a line midway between the plane of the xiphisternal junction and the transpyloric plane. The upper pole of each kidney is found about 5 cm from the midline (see Plane BB' in Fig. 3-24). The lower poles are situated along a plane midway between the transpyloric and transtuberular planes, 7 cm from the midline (see Plane CC' in Fig. 3-24). The hilum of each kidney lies along the transpyloric plane, 5 cm from the midline. Around these three points a bean-shaped figure 4 to 5 cm broad is drawn, two thirds of which lies medial to the lateral line. To indicate the position of the kidney from the back, a parallelogram may be used. Two vertical lines are drawn, the first 2.5 cm, the second 9.5 cm from the midline; the parallelogram is completed by two horizontal lines drawn at the level of the tip of the spinous process of the eleventh thoracic and the lower border of the spinous process of the third lumbar vertebra. The hilum is 5 cm from the midline at the level

of the spinous process of the first lumbar vertebra.

**Ureters.** The ureters are flattened tubes, 28 to 34 cm in length, which extend vertically, one on each side, from the kidneys to the bladder (Figs. 3-26; 3-27). Projected on the anterior aspect of the abdomen, the line of the ureter courses from the hilum of the kidney to the pubic tubercle. Their vertical course can be visualized posteriorly extending from the hilum of the kidney and passing practically across the posterior superior iliac spine (Fig. 3-26).

**Vessels** (Fig. 3-28). The course of the **inferior epigastric artery** can be approximated to the umbilicus. This line also indicates the lateral boundary of **Hesselbach's triangle**, the other boundaries of this triangle being the lateral border of the rectus abdominis muscle and the medial half of the inguinal

ligament. This triangle is of importance in the classification of **inguinal hernias**. There are two types of inguinal hernias, **indirect** (lateral, oblique, or congenital) and **direct** (medial or acquired). An *indirect inguinal hernia* is generally congenital, and the herniation commences lateral to the inferior epigastric artery. The path of the herniation follows the course of the spermatic cord or round ligament of the uterus through the inguinal canal, and hence it does not penetrate through Hesselbach's triangle. A *direct inguinal hernia* is usually due to some underlying weakness or defect in the lower anterior abdominal wall. The herniation occurs medial to the inferior epigastric artery and, therefore, commences through Hesselbach's triangle.

The **abdominal aorta** begins in the midline about 4 cm above the transpyloric line and

**Fig. 3-26.** Projection showing the average position of certain abdominal and pelvic viscera in the female. Anterior view. (Eycleshymer and Jones, 1925.)

**FIG. 3-27.** Projection showing the average position of the female pelvic organs. Lateral view. (Eycleshymer and Jones, 1925.)

extends to a point 2 cm below and to the left of the umbilicus (AA', Fig. 3-28). The point of bifurcation of the abdominal aorta corresponds to the level of the fourth lumbar vertebra. A line drawn from that site to a point midway indicates the course of the common iliac artery and one of its branches, the external iliac.

Of the larger branches of the abdominal aorta, the **celiac artery** is 4 cm above the transpyloric line. The **superior mesenteric artery** is 2 cm above and the **renal arteries** are 2 cm below the same line. The **inferior mesenteric artery** is 4 cm above the bifurcation of the abdominal aorta (Fig. 3-28).

**Nerves.** The skin of the anterior abdominal wall is innervated by anterior and lateral cutaneous branches of spinal nerves T7 through L1. These course around the trunk in a manner that could be represented by lines continuing those of the bony ribs. The termination of the **seventh thoracic nerve** is at the level of the xiphoid process; the **tenth** reaches the vicinity of the umbilicus; the

**twelfth** ends about midway between the umbilicus and the upper border of the symphysis pubis. The **first lumbar nerve** courses parallel to the thoracic nerves. Its **iliohypogastric** branch becomes cutaneous above the subcutaneous inguinal ring, while its **ilioinguinal** branch becomes cutaneous by penetrating through the ring.

## The Perineum

A line drawn transversely between the ischial tuberosities divides the **perineum** into a **posterior or rectal triangle** and an **anterior or urogenital triangle** (see Fig. 6-38). This line passes through the **central tendinous point** of the perineum, which is situated in the female about 2.5 cm anterior to the center of the anal aperture, or, in the male, midway between the anus and the reflection of the skin onto the scrotum.

**RECTAL EXAMINATION** (Fig. 3-29). A finger inserted through the anal orifice is compressed by the **external anal sphincter**, passes into the region of the **internal anal sphincter**, and more deeply encounters the resistance of the **puborectalis**; beyond this it may reach the lowest of the **transverse rectal folds**. Anteriorly, the **urethral bulb** and the **membranous urethra** are first identified, and then about 4 cm deep to the anal orifice in the male the **prostate** is felt. Beyond the prostate, the **seminal vesicles**, if enlarged, and the **fundus** of the **bladder**, when distended, are palpable. On either side of the anus is the **ischiorectal fossa**. Posterior to the anus can be felt the **anococcygeal body**, the pelvic surfaces of the **coccyx** and lower end of the **sacrum**, and the **sacrospinous ligaments**.

Additionally, rectal examination in the female allows the posterior wall and **fornix** of the **vagina**, and the **cervix** and **body** of the **uterus** to be felt in front, while somewhat laterally the **ovaries** can just be reached.

**SUPERFICIAL MALE UROGENITAL ORGANS.** The **penis** and the **testes** within their scrotal sac constitute the male superficial urogenital organs. The penis consists of two **corpora cavernosa penis**, which can be followed backward to their **crura** attached to the sides of the pubic arch, and the **corpus spongiosum penis**, the middle portion, which is tra-

**Fig. 3-28.** The front of the abdomen showing the surface projection of the arteries and the inguinal canal. The line AA' is drawn at the level of the highest points of the iliac crests. Observe that the region bounded by the inguinal ligament, the linea semilunaris (lateral border of the rectus abdominis muscle), and the inferior epigastric artery is the triangle of Hesselbach.

versed by the urethra. The distal portion of the corpus spongiosum penis is the **glans penis**, which is covered by the **prepuce**. The external urethral orifice can be examined at the tip of the glans penis, and the course of the urethra can be traced along the under-surface of the penis to the **bulb**, which is situated immediately in front of the central point of the perineum. The **testis** can be palpated through the wall of the **scrotum** on either side. It lies toward the back of the scrotum, and along its posterior border the **epididymis** can be felt. Passing upward along the medial side of the epididymis is the **spermatic cord**, which is palpable as far as the superficial inguinal ring.

**SUPERFICIAL FEMALE UROGENITAL ORGANS** (Figs. 3-26; 3-27). The female urogenital structures that are observable superficially include the **labia majora**, the **labia minora**, and the **clitoris**. The labia majora are two prominent and rounded folds of skin covering fatty and areolar tissue which extend from a site anterior to the anus to the **mons**

**pubis**, a soft mound of tissue in front of the symphysis pubis. Between the labia majora are two smaller and more narrow longitudinal folds, the labia minora. In the **puddendal cleft** between the labia minora are the openings of the **vagina** and **urethra**. In the virgin the vaginal opening is partly closed by a thin fold of mucous membrane, the **hymen**. After coitus the remains of the hymen are represented by small rounded elevations called the carunculae hymenales. Between the hymen and the frenulum of the labia minora is the **fossa navicularis**, while in the grooves between the hymen and the labia minora, the small openings of the **greater vestibular (Bartholin's) glands** can be seen. These glands, when enlarged, can therefore be felt on either side of the posterior part of the vaginal orifice. The clitoris, composed of erectile tissue, is situated in the midline anterior to the urethral orifice. It is palpable at the anterior ends of the labia minora and is an organ homologous to the male penis.

**VAGINAL EXAMINATION** (Fig. 3-30). With the

**FIG. 3-29.** The digital rectal examination. With the gloved index finger the anal canal in both sexes can be examined for tumors or other pelvic problems for a distance of about three inches. In the male the prostate gland and seminal vesicle can be palpated anteriorly. In the female the posterior wall of the vagina and the uterine cervix may be explored and by moving the finger laterally, the uterine tubes and ovaries may be felt.

examining finger inserted into the vagina the following structures can be palpated through its posterior wall from below upward: the **anal canal**, the **rectum**, and the **rectouterine excavation**. Projecting into the roof of the vagina is the vaginal portion of the uterine cervix with its external uterine orifice. In front of and behind the cervix the anterior and posterior **vaginal fornices** can be examined. With a finger still in the vagina and with the other hand exerting pressure on the abdominal wall, the entire **cervix** and **body of the uterus** as well as the **uterine tubes** and **ovaries** can be palpated. If a speculum is introduced into the vagina, its walls, the vaginal portion of the cervix, and the external uterine orifice can all be visually examined.

The external urethral orifice lies in front of the vaginal opening, and the angular gap in which the orifice is situated between the two converging labia minora is termed the **vestibule**. The urethral canal in the female is easily dilatable and can be explored with the finger. About 2.5 cm in front of the external orifice of the urethra are the **glans** and **prepuce of the clitoris**, and still farther forward is the **mons pubis**.

## The Upper Limb

**BONES.** The clavicle can be felt throughout its entire length (Figs. 3-17; 3-18). It is a curved bone and its extremities are enlarged both medially, where it articulates with the

**FIG. 3-30.** The digital vaginal examination. Digital palpation of the vaginal walls also allows for direct examination of the uterine cervix, as well as palpation of the uterus, bladder, and urethra anteriorly and the uterine tubes and ovaries laterally.

**sternum**, and laterally, where it articulates with the **acromion** of the **scapula**. The clavicle is fractured more frequently than any other bone in the body.

The only parts of the **scapula** (Figs. 3-19; 3-31) that are truly subcutaneous are the **spine** and **acromion**, but the **coracoid process**, the **vertebral border**, the **inferior angle**, and to a lesser extent the **axillary border** can also be readily palpated. The acromion and spine are recognizable surface landmarks throughout their entire extent, forming with the clavicle the arch of the shoulder. The acromion forms the point of the shoulder; it joins the clavicle at an acute angle—the **acromial angle**—slightly medial to, and behind the tip of the acromion. The scapular spine can be felt as a distinct ridge, marked on the surface as an oblique depression which becomes less distinct and ends in a slight dimple a little lateral to the spinous processes of the vertebrae (Figs. 3-11, 3-31). The spine of the scapula helps to define the

muscle-filled **infraspinatus** and **supraspinatus fossae**. Below the spine the contour of the infraspinatus muscle can readily be inspected, whereas above the spine the supraspinatus muscle is covered smoothly by the trapezius (Fig. 3-31). The coracoid process is situated about 2 cm below the junction of the middle and lateral thirds of the clavicle. It is covered by the anterior border of the deltoid, and thus lies a little lateral to the infraclavicular fossa or depression which marks an interval bounded by the pectoralis major, the deltoid, and the clavicle called the **deltopectoral triangle**. Through this triangle the superficially coursing **cephalic vein** penetrates the deep fascia to enter the **axillary vein** just below the level of the clavicle.

The **humerus** (Figs. 3-32, 3-33, 3-34) is almost entirely surrounded by muscles, and the only parts that are strictly subcutaneous are small portions of the **medial** and **lateral epicondyles**. Additionally, however, the **tubercles** and a part of the **head** of the hu-

**FIG. 3-31.** Cross-section, viewed from above, through the right arm at a level immediately below the proximal one-third of the humerus.

**FIG. 3-32.** Cross section, viewed from above, through the right arm, a little below the middle of the shaft of the humerus.

**Fig. 3-33.** Posterior view of the back and upper extremities demonstrating surface muscle contours.

merus can be felt under the skin and muscles by which they are covered. The greater **tubercle** forms the most prominent bony point of the shoulder, extending even beyond the acromion. This tubercle, covered by the deltoid muscle, forms the roundness of the lateral aspect of the shoulder. On the distal end of the humerus the medial and lateral epicondyles can be palpated on either side of the elbow joint. Of these, the medial epicondyle is the more prominent, but the **medial supracondylar ridge** passing upward from it is much less marked than the lateral, and as a rule is not palpable.

The most prominent part of the **ulna**, the **olecranon**, can easily be identified behind the elbow joint. The prominent dorsal border of the ulna can be felt along its whole length in the forearm (Figs. 3-35; 3-36), and

the **styloid process** forms a prominent tubercle at the distal end of the ulna. It is continuous above with the dorsal border and ends below in a blunt apex at the level of the wrist joint.

Below the lateral epicondyle of the humerus a portion of the head of the **radius** is palpable. When the forearm is extended, a depression can be observed in the posterolateral aspect of the elbow joint. Rotation of the head of the radius can be palpated in this depression while the subject pronates and supinates the forearm. The upper half of the body of the radius is obscured by muscles (Figs. 3-35; 3-36); the lower half, though not subcutaneous, can be traced downward to the lateral aspect of the wrist joint. Here, a conical projection of bone, the **styloid process** of the radius, can be observed to project

**Fig. 3-34.** Cross section, viewed from above, through the right arm 2 cm. proximal to the medial epicondyle of the humerus.

5 to 6 mm distal to the styloid process of the ulna.

The radius and ulna articulate distally with the **carpal bones** at the wrist joint. On the front of the wrist are two subcutaneous eminences: one, on the radial side, the larger and flatter, is produced by the adjacent tu-

bercle of the **scaphoid bone** and ridge of the **trapezoid bone**; the other, on the ulnar side, is formed by the **pisiform bone**. The rest of the palmar surface of the carpal bones is covered by tendons and the transverse carpal ligament, and is entirely concealed. An exception is the hamulus (or hook) of the ha-

**Fig. 3-35.** Cross section, viewed from above, through the right forearm at the level of the radial (bicipital) tuberosity.

FIG. 3-36. Cross section, viewed from above, through the middle of the right forearm.

**mate bone** on the ulnar side of the wrist, which, however, is also somewhat difficult to define. On the dorsal surface of the carpus only the **triquetral bone** can be clearly recognized by palpation.

Distal to the wrist the dorsal surfaces of the **metacarpal bones**, covered by the extensor tendons, are visible only in very thin hands. The dorsal surface of the fifth metacarpal bone is, however, subcutaneous throughout almost its entire length. The heads of the metacarpal bones are their distal extremities, and they can be plainly seen and felt, rounded in contour and standing out under the skin when the fist is clenched, forming the prominences of the knuckles. The head of the third metacarpal is the most prominent.

The enlarged ends of the **phalanges** can be easily felt. When the digits are bent the proximal ends of the phalanges form prominences. In the joints between the first and second phalanges, these prominences are slightly hollow, but they are flattened and square-shaped between the second and third.

**ARTICULATIONS.** The **sternoclavicular joint** is subcutaneous, and its position can be identified by the enlarged sternal extremity of the clavicle, lateral to the cord-like sternal head of the sternocleidomastoid. Upon relaxing this muscle, a depression between the end of the clavicle and the sternum can be felt, defining the position of the joint. The sternoclavicular joint is the only articulation between the upper extremity and the trunk.

Posterior to this joint on the right side is found the pleural covering of the right lung along with the right brachiocephalic artery and vein. On the left side, in addition to the pleura, the left brachiocephalic vein, the left common carotid artery, and the thoracic duct underlie this joint.

The position of the **acromioclavicular joint** can generally be ascertained by determining the slightly enlarged acromial end of the clavicle, which usually projects somewhat above the level of the acromion, thereby overriding it. Sometimes this enlargement is considerable, forming a rounded eminence.

The **shoulder joint** is deeply seated and cannot be palpated. It should be appreciated, however, that the **glenoid cavity of the scapula**, into which the spherical head of the humerus fits, is exceedingly shallow. This, along with the looseness of the articular capsule, allows for the elegant freedom of movement at that joint. At the same time, however, the shoulder joint is weakly constructed. Although it receives some protection from tendons, muscles, and the coracoid and acromial processes and their associated ligaments, *dislocations occur more frequently at this joint than at any other.* These usually are directed initially inferiorly to assume a *subglenoid* position, but then secondarily the head of the humerus may be directed anteriorly, beneath the coracoid process of the clavicle, or posteriorly, beneath the acromion or spine of the scapula.

The **elbow joint** consists of two articulations: the **humeroulnar**, in which the **trochlea** of the humerus fits into the **trochlear notch** of the ulna, and the **humeroradial**, in which the **capitulum** of the humerus articulates with the **head** of the radius. Behind the curved trochlear notch of the ulna is the thick and prominent **olecranon**. When the forearm is flexed, the olecranon becomes the pointed bony eminence of the elbow. When the forearm is extended, the olecranon fits snugly between the epicondyles of the humerus, forming a continuous line between forearm and arm. If the forearm is slightly flexed, a curved crease or fold with its convexity downward is seen in front of the elbow, extending from one epicondyle to the other; the elbow joint is slightly distal to the center of the fold. The position of the humeroradial joint can be ascertained by feeling for a slight groove or depression between the head of the radius and the capitulum of the humerus, at the back of the elbow joint.

In addition to their articulation with the humerus, the radius and ulna articulate with each other proximally, below the elbow joint, along their shafts by way of the interosseous membrane, and distally, just above the carpal bones. The position of the **proximal radioulnar joint** is marked on the surface at the back of the elbow by a slight depression, which indicates the position of the head of the radius. The site of the **distal radioulnar joint** can be defined by feeling for the slight groove at the back of the wrist between the prominent head of the ulna and the lower end of the radius, when the forearm is pronated.

Of the three transverse skin furrows on the front of the wrist, the middle corresponds fairly accurately with the **wrist joints**, while the most distal indicates the position of the **midcarpal articulation**.

The **metacarpophalangeal** and **interphalangeal joints** are readily available for surface examination. The former are situated just distal to the prominences of the knuckles; the latter are sufficiently indicated by the furrows on the palmar and the wrinkles on the dorsal surfaces of the fingers.

**MUSCLES.** The large muscles that arise on the trunk and insert on the shoulder girdle form the superficial layers of muscle of the thorax, both on the chest and on the back. The **pectoralis major** (Figs. 3-18; 3-37), **lati-**

**simus dorsi** (Fig. 3-31), and **trapezius** (Figs. 3-11; 3-13; 3-31) muscles are easily visible in most subjects. The **serratus anterior** (Figs. 3-13; 3-37) is mostly concealed by the scapula, but its serrations, interdigitating with the external oblique on the anterolateral aspect of the chest, are usually visible in muscular or thin subjects (Fig. 3-37). The **pectoralis minor** is completely hidden by the pectoralis major.

The **deltoid** (Figs. 3-11; 3-13; 3-31) and the **teres major** (Fig. 3-37) are prominent on the shoulder. The **biceps** (Fig. 3-37), **coracobrachialis**, and **brachialis** are easily distinguishable on the anterior, and the **triceps** (Fig. 3-37) on the posterior aspect of the arm. The muscles of the forearm form two groups: a **medial group**, consisting of the flexors and the pronators arising from the medial epicondyle, and a **lateral group**, comprised of the extensors and supinators arising from the lateral epicondyle. Many tendons of the individual forearm muscles can be identified at the wrist (Fig. 3-37).

The **antecubital fossa**, in front of the elbow joint, is triangular in shape. Its boundaries are a lateral group forearm muscle, the **brachioradialis**, a medial group muscle, the **pronator teres**, and a line joining the medial and lateral epicondyles above. The brachial and supinator muscles form the floor of the fossa, and within it the **brachial artery** and **median nerve** may be palpated. Through the fossa courses the **median cubital vein**, making it readily accessible clinically for intravenous injections or blood withdrawal.

The **synovial tendon sheaths** of the palm and dorsum of the hand cannot be identified except as they follow the various tendons across the wrist and distally in the fingers.

**ARTERIES.** Above the middle of the clavicle the pulsation of the **subclavian artery** can be detected by pressing downward, backward, and medialward against the first rib. The pulsation of the **axillary artery** as it crosses the second rib can be felt below the middle of the clavicle just medial to the coracoid process. The course of the artery can be followed along the lateral wall of the axilla to the medial border of the coracobrachial muscle. The **brachial artery** can be recognized along practically its entire extent, coursing down the medial margin of the biceps. The **radial artery** becomes superficial over the lower end of the radius, between the styloid process and flexor carpi

**FIG. 3-37.** Anterior view of head and chest and the upper extremities demonstrating surface muscular contours.

radialis. It is used clinically for observations of the pulse (Figs. 3-38; 3-40). The **ulnar artery** also becomes more superficial in its course down the medial aspect of the distal forearm, and at the wrist, the ulnar nerve lies just medial to the artery. Both the ulnar and the radial arteries enter the hand (Fig. 3-40).

In the hand the **superficial palmar arch** (Fig. 3-40), derived mainly from the ulnar artery, can be indicated by a line starting from the radial side of the pisiform bone and curving distalward and lateralward as far as the base of the thumb, with its convexity toward the fingers. The summit of the arch is usually on a level with the ulnar border of the outstretched thumb. The **deep palmar arch** (Fig. 3-40), derived mainly from the radial artery, is practically transverse, and is situated deeper in the hand and somewhat more distal to the superficial palmar arch.

**VEINS.** The superficial veins of the upper limb are easily rendered visible by compressing the proximal trunks. The **basilic vein** forms from the venous network on the ulnar side of the dorsal hand and then passes up the medial aspect of the forearm and arm

to join the more deeply coursing **brachial vein** to form the **axillary vein**. The **cephalic vein** (Fig. 3-13) commences on the radial aspect of the dorsal hand, courses up the lateral aspect of the forearm and arm, and passes in the groove between the deltoid and pectoralis major muscles to enter the axillary vein. In front of the elbow, the **median cubital vein** communicates between the cephalic and basilic veins.

**NERVES** (Figs. 3-38; 3-39). The uppermost trunks of the **brachial plexus** are palpable for a short distance above the clavicle as they emerge from under the lateral border of the sternocleidomastoid; the larger nerves derived from the plexus can be rolled under the finger against the lateral axillary wall, but cannot be identified with certainty at this site.

The **axillary nerve** (Fig. 3-39) emerges from the posterior cord of the brachial plexus. It then courses around the shaft of the humerus under cover of the deltoid muscle.

The **musculocutaneous nerve** (Fig. 3-32) lies deep within the musculature of the

FIG. 3-38. Anterior aspect of right upper extremity, showing surface projection of bones, arteries, and nerves.

FIG. 3-39. Posterior aspect of right upper extremity showing surface projection of bones and nerves.

FIG. 3-40. Palm of left hand, showing position of skin creases and bones, and surface projection for the palmar arterial arches.

flexor compartment in the arm, but becomes superficial about 7.5 cm above the cubital fossa, lateral to the tendon of the biceps brachii.

The line of the **median nerve** (Figs. 3-32; 3-33; 3-38) in the arm is practically the same as that for the brachial artery and may even be injured when pressure is applied to the artery. Anterior to the elbow, the nerve lies medial to the artery in the center of the cubital fossa. Descending the forearm under cover of the anterior forearm muscles, it reaches the wrist lateral to the palmaris longus, and enters the palm of the hand by passing deep to the flexor retinaculum within the carpal tunnel.

The **ulnar nerve** (Figs. 3-34 to 3-36; 3-38) also follows the course of the brachial artery in the upper arm, then diverges and descends in the groove behind the medial epicondyle over the elbow, where it lies just beneath the skin. In the upper forearm it descends along the ulnar side under the flexor carpi ulnaris, while more distally in the forearm it courses with the ulnar artery, with which it enters the ulnar aspect of the palm of the hand superficial to the flexor retinaculum.

The **radial nerve** (Figs. 3-32; 3-33; 3-34; 3-35; 3-38; 3-39) derives from the posterior cord of the brachial plexus and achieves the posterior compartment of the arm by cours-

ing deeply between the medial and long heads of the triceps brachii. Here it is accompanied by the profunda brachii artery along the spiral groove of the humerus. Because of this relationship with the bone, it is liable to injury in fractures of the humerus or may be severely compressed by pressure. Supplying the extensor compartment muscles in the forearm, the radial nerve eventually achieves the dorsum of the hand, which it helps to innervate with sensory fibers.

## The Lower Limb

**BONES.** The pelvis or hip bones are largely covered with muscle, so that only at a few sites do they lie immediately beneath the skin surface. The highest part of the pelvis on each side is the thick **iliac crest**. This can be easily palpated, except in very obese individuals, and can be traced anteriorly to the **anterior superior iliac spine**, and posteriorly to the **posterior superior iliac spine**. The latter bony spine is indicated by a slight depression. On the outer lip of the crest, about 5 cm behind the anterior superior spine, is the prominent **iliac tubercle**. In thin subjects the **pubic tubercle**, located near the superior lateral border of the symphysis pubis, is very apparent, but in the obese it is obscured by the pubic fat. It can, however, be detected by following the tendon of origin of the adductor longus superiorly. Additionally, the inguinal ligament can be followed from the anterior superior iliac spine to the pubic tubercle. Another part of the bony pelvis that is accessible to touch is the **ischial tuberosity**, situated beneath the gluteus maximus. When the hip is flexed, this tuberosity can easily be felt, since it is then not covered by muscle.

The **femur** (Figs. 3-41 to 3-43) is enveloped by muscles, so that the only palpable parts are the lateral surface of the **greater trochanter** and the lower expanded end of the bone. The greater trochanter can be felt on the upper lateral aspect of the thigh. It is generally indicated by a depression, owing to the thickness of the gluteus medius and gluteus minimus which project above it. The greater trochanter becomes a more prominent protuberance if the thigh is flexed and crossed over the opposite one. At the lower end of the femur the **lateral condyle** is more easily felt than the **medial**. Both **epicondyles** can

be readily identified, and at the summit of the medial epicondyle the sharp **adductor tubercle** can be recognized without difficulty.

The anterior surface of the **patella** is subcutaneous (Fig. 3-44). This sesamoid bone lies within the tendon of the quadriceps femoris muscle, and when the muscle is relaxed, the patella can be moved from side to side. Upon flexion of the leg the patella recedes between the condyles of the femur, but upon extension it lies anterior to the condyles. By its position, the patella helps to protect the knee joint from injury, strengthening the structure of the quadriceps tendon as well.

A considerable portion of the **tibia** or shin bone is subcutaneous (Figs. 3-46; 3-47). At the upper end the **tibial condyles** can be felt just below the knee joint. In front of the upper

**FIG. 3-41.** Anterior view of lower limbs and abdomen demonstrating surface muscular contours.

**FIG. 3-42.** Cross section through the right thigh, viewed from above, at the level of the apex of the femoral triangle.

end of the bone, between the condyles, is an oval eminence, the **tibial tuberosity**, which is continuous below with the anterior crest of the bone. At the lower end of the bone, the **medial malleolus** (Fig. 3-44) forms a broad prominence, situated at a higher level and somewhat farther forward than the **lateral malleolus** of the **fibula** (Fig. 3-44). The only subcutaneous parts of the fibula are the **head**, the lower part of the **body**, and the **lateral malleolus**. The lateral malleolus is a narrow elongated prominence, from which the lower third or half of the lateral surface of the body of the bone can be traced upward (Fig. 3-44).

It is difficult to distinguish the individual **tarsal bones** on the dorsum of the foot by palpation alone. An exception is the **head** of the **talus**, which forms a rounded projection in front of the ankle joint when the foot is forcibly extended. The whole dorsal surface of the foot has a smooth convex outline, the

summit of which is the ridge formed by the head of the talus, the **navicular**, the **intermediate cuneiform**, and the **second metatarsal bone**. On the medial side of the foot the medial process of the **tuberosity** of the **calcaneus** and the ridge separating the posterior from the medial surface of the bone are distinguishable; in front of this, and below the medial malleolus, is the **sustentaculum tali**. The **tuberosity** of the **navicular** is palpable about 2.5 to 3 cm in front of the medial malleolus.

Farther forward, the ridge formed by the base of the short and thick **first metatarsal bone** can be felt. The head of the first metatarsal is large, and its prominence on the plantar aspect of the foot is called the ball of the large toe. Beneath the base of the first phalanx is the medial **sesamoid bone**. On the lateral side of the foot, in the region of the heel, the most posterior bony point is the lateral process of the tuberosity of the calca-

**FIG. 3-43.** Cross section, viewed from above, through the middle of the right thigh. Observe the sciatic nerve coursing along the posterior surface of the adductor magnus muscle.

**FIG. 3-44.** Cross section, viewed from above, through the right thigh 4 cm proximal to the adductor tubercle of the femur. Note that the neurovascular structures have entered the proximal part of the popliteal fossa.

**FIG. 3-45.** Right side of lower limbs to show surface contours of muscles and bones.

neus. In front of this the greater part of the lateral surface of the calcaneus is subcutaneous. Farther forward the base, body, and head of the **fifth metatarsal bone** are prominent.

The dorsal surfaces of the **metatarsal bones** are easily defined; the plantar surfaces are obscured by muscles. The **phalanges** in their whole extent are readily palpable.

**ARTICULATIONS.** The **hip joint** is deeply seated and cannot be palpated. The interval between the tibia and femur can always be felt; if the **knee joint** is extended this interval lies at a higher level than the apex of the patella, but if the leg is slightly flexed it lies directly behind the apex.

The **ankle joint** can be felt on either side of the extensor tendons, and during plantar flexion of the foot, the superior articular sur-

face of the talus is palpable below the anterior border of the lower end of the tibia.

**MUSCLES** (Figs. 3-41 to 3-45). The prominent muscles on the anterior aspect of the thigh are the **quadriceps femoris** and the **sartorius**, while laterally the **tensor fasciae latae** attaches to a broad tendon, the **iliotibial band**, which extends downward to the knee joint. At the medial side of the thigh are the **adductors**, and on the posterior thigh are the three hamstrings, medially the **semitendinosus** and **semitendinosus** and laterally the **biceps femoris**. Above the thigh, the prominence of the buttock is caused mostly by the **gluteus maximus**.

Below the knee joint, the contour of the calf on the back of the leg is due to the **gastrocnemius** and **soleus** muscles, which terminate at the heel in the **tendon of Achilles** or **tendo calcaneus** (Figs. 3-46 to 3-48). Lateral to the anterior border of the tibia (or shin bone), the **tibialis anterior** and the **peroneus longus** and **brevis** can usually be recognized (Figs. 3-46, 3-47).

The **femoral triangle** (Fig. 3-44) is bounded above by the **inguinal ligament**, laterally by the medial border of the **sartorius** muscle, and medially by the medial border of the **adductor longus**. A large superficial vein of the lower limb, the **great saphenous vein**, penetrates this triangle by way of the **hiatus saphenus** to join the **femoral vein**. The center of this hiatus is about 4 cm below and lateral to the pubic tubercle; its vertical diameter measures about 4 cm and its transverse about 1.5 cm. Medial to the femoral vein is the **femoral ring**. This ring is about 1.25 cm lateral to the pubic tubercle, and it is the oval-shaped cranial aperture of the femoral canal through which femoral hernias may occur. This type of hernia is about three times more frequent in females than in males.

Midway down the medial aspect of the thigh is located the **adductor canal**. This canal begins at the apex of the femoral triangle and lies deep to the vertical part of the **sartorius** muscle; for this reason, it is also sometimes called the **subsartorial canal**. Through the adductor canal passes the **femoral artery** in order to achieve the back of the knee in the **popliteal fossa** (Fig. 3-42). This important fossa is bounded above by the medial and lateral hamstrings, and below by the medial and lateral heads of the

**Fig. 3-46.** Cross section, viewed from above, through the right leg, 9 cm. distal to the knee joint. Observe the relationship of the tibial nerve with the posterior tibial artery and the deep peroneal nerve with the anterior tibial artery. Note also the superficial peroneal nerve in the lateral compartment.

**Fig. 3-47.** Cross section, viewed from above, through the right leg, 6 cm. proximal to the tip of the medial malleolus.

**FIG. 3-48.** Right side of leg to show surface contours of muscles and bones.

gastrocnemius muscle. In this fossa the **popliteal artery** and **sciatic nerve** are covered only by subcutaneous tissue and fat, and through it the **small saphenous vein** joins the **popliteal vein**.

**ARTERIES.** The **femoral artery** enters the anterior thigh midway between the anterior superior iliac spine and the pubic tubercle, just below the inguinal ligament. Its pulsations can be felt at this point, but they become increasingly difficult to detect as the artery courses inferiorly toward and into the adductor canal. When the leg is flexed at the knee joint, the pulsation of the **popliteal artery**, which is the continuation of the femoral artery, can easily be detected in the popliteal fossa behind the joint.

On the lower part of the front of the tibia, the **anterior tibial artery** becomes superficial (Fig. 3-47) and can be traced over the ankle

joint into the dorsal foot as the **dorsalis pedis artery**. This latter vessel can be followed to the proximal end of the first intermetatarsal space. On the back of the leg, the pulsation of the **posterior tibial artery** becomes detectable near the lower end of the tibia, and is easily felt behind the medial malleolus.

**VEINS.** By compressing the proximal trunks, the venous arch on the dorsum of the foot, together with the **great** and **small saphenous veins** leading from it, is rendered visible.

**NERVES.** The only nerve of the lower limb that can be located by palpation is the **common peroneal** as it winds around the lateral side of the neck of the fibula. Because of its subcutaneous location and its position adjacent to bone, this nerve is quite vulnerable to injury at this site.

## Osteology

The study of bones is called **osteology**. Bones provide a framework for the body, and when assembled in their proper position, they form the **skeleton** (Fig. 4-1). In the living body, bones are frequently held in position by strong fibrous bands, the **ligaments**, which form articulations or **joints**. Attached to bones across the joints are most of the **muscles** of the body, and muscular contraction results in the movement of bones and their associated body parts. In addition to providing internal support for the body, the skeleton protects the vital organs of the head and chest by forming the cranial and thoracic cavities. Because of its large mineral content, bone is a hard unyielding tissue and is ideally suited for the mechanical functions of support, protection, and movement. In life it is also a dynamic substance and is importantly involved with other tissues and organs in the metabolism of calcium. The interior of bones contains the **bone marrow**, which consists of the blood-forming, hemopoietic tissue.

In the skeleton of the adult there are 206 distinct bones, as follows:

	Vertebral column . . . .	26	
Axial Skeleton	Skull . . . . .	28	
	Hyoid bone . . . . .	1	
	Ribs and sternum . . .	25	
			80
Appendicular Skeleton	Upper extremities . . .	64	
	Lower extremities . . .	62	
			126
Total . . . . .			206

The patellae are included in this enumeration, but the smaller sesamoid bones are not; also, the sternum is considered as one bone. Bones can be classified into four general types according to their shape and form. **Long bones**, such as the humerus and femur, are found in the limbs (Fig. 4-1), whereas **short bones**, such as those in the hand and foot, are more compact and subjected to more limited movement. Other bones, illustrated by the parietal bones of the skull or the scapulae (Fig. 4-1), are **flat bones**, while **irregular bones** form the vertebral column (Fig. 4-1), as well as other structures.

### Ossification and Skeletal Development

The skeleton, like some other structures, is derived from **mesoderm**, which migrates from the primitive streak during the formation of the three primary germ layers. Its cells multiply, undergo certain changes, move into appropriate regions, and form cellular aggregates or sheets which can be recognized as the **membranous skeleton**. The cells of these primordia, except in certain parts of the cranium, soon elaborate an intercellular substance that converts the tissue into cartilage. After the **cartilaginous skeleton** is well established, centers of ossification appear which gradually spread to form the **bony skeleton**. In some of the cranial bones ossification centers arise in the membranous skeleton without the intervention of cartilage.

#### OSSIFICATION

The term **ossification** refers to the formation of bone. In the development of certain bones, such as those forming the roof and sides of the skull, bone formation occurs directly within clusters of primitive mesenchyme cells surrounded by a more definitive connective tissue membrane. In other bones, such as those in the limbs, the formation of bone occurs within rods of pre-existing cartilage. Hence, two forms of ossification are described: **intramembranous** and **endochondral**. The latter type is sometimes called intracartilaginous.

**INTRAMEMBRANOUS OSSIFICATION.** In the case of bones that are developed in membrane, no cartilaginous mold precedes the

**FIG. 4-1.** The skeleton as projected on the surface of the body. Ventral and dorsal views. (From Eycleshymer and Jones.)

appearance of bony tissue. The connective tissue membrane, which surrounds the centers of ossification, persists and ultimately forms the **periosteum**; it is composed of fibers and granular cells in a matrix. The peripheral portion is more fibrous, while in the interior the primitive mesenchymal cells differentiate into **osteoblasts**; the whole tissue is richly supplied with blood vessels. At the outset of the process of bone formation, a little network of eosinophilic extracellular spicules is noticed forming between the branching vascular elements. At their growth points, these rays consist of a network of fine clear fibers and osteoblast cells with an intervening ground substance. The fibers are termed **osteogenic fibers**, and are made up of fine collagen fibrils differing little from those of other connective tissue. The membrane soon assumes a dark and granular appearance from the deposition of calcium-containing crystals (hydroxyapatite) in the fibers and in the intervening matrix. As the bony trabeculae enlarge, some of the osteoblasts become surrounded by the newly deposited calcified material. With the deposition of mineral salts, the newly formed osteoid tissue again assumes a more transparent appearance, and the fibrils are no longer so distinctly seen. The involved osteoblasts form the corpuscles of the future bone, the spaces in which they are enclosed constituting the **lacunae**. As the osteogenic fibers grow toward the periphery, they continue to ossify and give rise to fresh bone spicules. Thus a network of woven bone is formed, the meshes of which contain blood vessels and a delicate connective tissue crowded with osteoblasts. The bony trabeculae thicken by the addition of fresh layers of bone formed by the osteoblasts on their surface. Subsequently, successive layers of bony tissue are deposited under the periosteum and around the larger vascular channels, which become the Haversian canals as the bone increases in thickness. The entrapped osteoblasts of developing bone become the **osteocytes** of mature bone, and these cells may well be importantly involved in the release of calcium from bone to blood.

**ENDOCHONDRAL OSSIFICATION.** Ossification in long bones of the extremities, in portions of the basal bones of the skull, and in the vertebrae, the sternum, the ribs, and the pelvis occurs in masses of pre-existing developed hyaline cartilage, which present a

model form of the fully ossified bone. In a long bone, which may be taken as an example (Fig. 4-2), the process commences in the center of the **diaphysis**, or **shaft**, and proceeds toward the extremities, called the **epiphyses**, which for some time remain cartilaginous. Subsequently a similar ossification process commences in one or more sites of the epiphyses and gradually extends through them. The epiphyses do not, however, become joined to the shaft of the bone by bony tissue until growth has ceased; between the diaphysis and either epiphysis a layer of cartilaginous tissue termed the **epiphyseal cartilage** persists for a definite period.

The first stage in the ossification of cartilage takes place at the **center of ossification**,

**FIG. 4-2.** Photograph of the upper half of the tibia of young girl, showing the proximal bony epiphysis, the cartilaginous epiphyseal plate, and the shaft or diaphysis. (From Bloom and Fawcett, *A Textbook of Histology*, W. B. Saunders Co., 1975.)

where cartilage cells enlarge and arrange themselves in rows (Fig. 4-3). The matrix in which they are embedded increases in quantity, so that the cells become separated from each other. Deposits of calcium-containing crystals now accumulate in this matrix, between the rows of cells, so that the cartilage cells become separated from each other by longitudinal columns of calcified matrix which appear granular and opaque. At some sites the matrix between two cartilage cells of the same row also becomes calcified, and transverse bars of calcified substance stretch across from one calcified column to another. Thus, there are longitudinal groups of cartilage cells enclosed in oblong cavities, the walls of which consist of calcified matrix and effectively cut off all nutrition from the cells. In consequence, the cells atrophy, leaving spaces called the **primary areolae**.

At the same time that this process occurs in the center of the solid bar of cartilage, certain changes are taking place on its surface. This is covered by a highly vascular membrane, the **perichondrium**, entirely similar to the embryonic connective tissue already described as constituting the basis of membrane bone. On its inner surface, that is, on the surface in contact with the cartilage, are gathered rows of osteoblasts. These cells form a thin layer of bony tissue, called a periosteal bone collar, between the perichondrium and the cartilage by the *intramembranous* mode of ossification already described. There are, then, in this first ossification stage of cartilaginous bone, two processes going on simultaneously: in the center of the cartilage, the formation of a number of oblong spaces, surrounded by calcified matrix and containing the withered cartilage cells, and on the surface of the cartilage, the formation of a layer of true membranous bone.

The second stage of intracartilaginous ossification (Fig. 4-3) occurs when blood vessels perforate the periosteal bone collar to invade the deeper osteogenic regions of the cartilage. Additionally, **osteoclasts**, or bone destroyers, make their appearance. These giant cells seem associated with the absorption of osteogenic matrix, possibly by their secretion of hydrolytic enzymes. Osteoclasts can be observed occupying minute chambers called **Howship's lacunae**, which, by erosion, they may have created themselves on the bone surface. There is evidence that osteoclasts are derived from the fusion of

**FIG. 4-3.** Osteogenesis. Subperiosteal stage of ossification in an embryonic long bone. 20 X. (Redrawn from Sobotta.)

mononuclear osteogenic cells, yet some may come from mononuclear cells in the blood such as monocytes. Regardless of their origin, as they come into contact with the calcified walls of the primary areolae, osteoclasts

cause a fusion of the original cavities, which creates larger spaces termed the secondary areolae or **medullary spaces**. These secondary spaces become filled with embryonic marrow, osteoblasts, and vessels, derived from the osteogenic layer of the periosteum (Fig. 4-4).

Traced thus far has been the formation of enlarged medullary spaces, the perforated walls of which are still formed by calcified cartilage matrix, containing an **embryonic marrow** derived from the osteogenic layer of periosteum, and consisting of blood vessels

and osteoblasts. At this time the walls of these secondary areolae are of only inconsiderable thickness, but they become thickened by the deposition of layers of true bone on their surface. This process takes place in the following manner: some osteoblasts in the embryonic marrow, after undergoing rapid division, arrange themselves in an epithelioid manner on the surface of the wall of the space. This layer of osteoblasts forms a bony stratum, and thus the wall of the space becomes gradually covered with a layer of true osseous substance in which some of the

**FIG. 4-4.** Endochondral bone formation proceeding from the center of the shaft of a long bone toward one of the two extremities. 40  $\times$ . (Redrawn from Sobotta.)

bone-forming cells are included as bone corpuscles. The next step in the process consists in the removal of these primary bone spicules by the osteoclasts. One of these giant cells may be found lying in a Howship's lacuna at the free end of each spicule. The removal of the primary spicules goes on *pari passu* with the formation of permanent bone by the periosteum, and in this way the medullary cavity of the body of the bone is formed.

Commencing in the center of the diaphysis of the cartilaginous bony model, this series of changes gradually proceeds toward the extremities of the bone, so that in a specimen of ossifying bone all the aforementioned changes may be seen at different sites, from true bone at the center of the shaft to hyaline cartilage at the extremities.

*While the ossification of the cartilaginous body is extending toward the articular ends, the cartilage immediately in advance of the osseous tissue continues to grow until the length of the adult bone is reached.*

During the period of growth the articular end, or epiphysis, remains for some time entirely cartilaginous, then a bony center appears within it, initiating at this site, as well, the process of intracartilaginous ossification. This is a **secondary center of ossification**. The epiphysis remains distinct from the ossified diaphysis by a narrow cartilaginous zone called the **epiphyseal plate**. This, too, ultimately ossifies, and the histologic distinction between diaphysis and epiphysis is obliterated, the bone assuming its completed form and shape. Similar events also occur in bony processes that ossify separately, such as the trochanters of the femur. The bones continue to grow until the body has acquired its full stature, increasing in length by ossification toward the epiphyses and in circumference by the deposition of new bone from the deeper inner layer of the periosteum. At the same time bone resorption takes place from within, thereby enlarging the medullary marrow cavities. A review of the stages in the development of a typical long bone is presented in the diagrams of Figure 4-5.

Permanent bone, when first formed by the periosteum, is spongy or **cancellous** in structure. Later, as osteoblasts contained in its spaces become arranged in the concentric layers characteristic of the **Haversian systems**, the bone assumes the more solid structure of **compact** bone.

The number of ossification centers varies in different bones. In most of the short bones, ossification commences at a single central site, and proceeds toward the surfaces. In long bones there is a central point of ossification for the shaft or diaphysis, and one or more for each extremity, or epiphysis. That for the diaphysis is the first to appear. The times of union of the epiphyses with the diaphysis vary inversely with the dates at which their ossifications began (with the exception of the fibula). This process also influences the direction of growth of the nutrient arteries of the bones. Thus, the nutrient arteries of the bones of the arm and forearm are directed toward the elbow, since the epiphyses at this joint become united to the diaphyses before those at the opposite extremities at the shoulder and wrist. In the lower limb, on the other hand, the nutrient arteries are directed away from the knee: that is, upward in the femur and downward in the tibia and fibula. In these bones it is observed that the upper epiphysis of the femur, and the lower epiphyses of the tibia and fibula unite first with the diaphyses. Where there is only one epiphysis, the nutrient artery is directed toward the opposite end of the bone; for example, toward the acromial end of the clavicle, toward the distal ends of the metacarpal bone of the thumb and the metatarsal bone of the great toe, and toward the proximal ends of the other metacarpal and metatarsal bones.

## SKELETAL DEVELOPMENT

**VERTEBRAL COLUMN.** The central axis of the embryo around which the vertebrae develop is the notochord. This rod of cells lies in the median line between the neural tube and the primitive gut, extending from the level of the midbrain to the end of the tail. The somites in the paraxial mesoderm on either side of the neural tube give rise to three primordia, the **sclerotome**, **myotome**, and **dermotome**. The cells of the sclerotome eventually form the vertebrae, as well as other structures. During the fourth embryonic week these cells multiply rapidly and migrate toward the notochord, forming a mesenchymal layer on either side. The **segmental primordia** of the individual vertebrae are still recognizable, but soon each sclerotome differentiates into a densely arranged cau-

**FIG. 4-5.** Diagram of the development of a typical long bone as shown in longitudinal sections (A to J) and in cross sections A', B', C', and D' through the centers of A, B, C, and D. Pale blue, cartilage; purple, calcified cartilage; black, bone; red, arteries. A, Cartilage model. B, Periosteal bone collar appears before any calcification of cartilage. C, Cartilage begins to calcify. D, Vascular mesenchyme enters the calcified cartilage matrix and divides it into two zones of ossification. E, F, Blood vessels and mesenchyme enter upper epiphyseal cartilage and the epiphyseal ossification center develops in it. G, A similar ossification center develops in the lower epiphyseal cartilage. H, As the bone ceases to grow in length, the lower epiphyseal plate disappears first, I, and then the upper epiphyseal plate, J. The bone marrow cavity then becomes continuous throughout the length of the bone, and the blood vessels of the diaphysis, metaphyses, and epiphyses intercommunicate. (From Bloom and Fawcett, *A Textbook of Histology*, W. B. Saunders Co., 1975).

**Fig. 4-6.** Diagrams showing the manner in which each vertebral centrum is developed from portions of two adjacent somites or body segments. A, The segmental structure of the sclerotome differentiates into a more dense caudal portion and a more loosely arranged cranial portion around the notochord. B, The lateral and somewhat cranial migration of some of the densely arranged cells forms a costal process laterally and the primordium of the intervertebral disc cranially as seen in C. C, Note the disc formed by densely arranged cells and the centrum of the vertebrae formed by parts of two adjacent sclerotomes.

dal portion and loosely arranged cranial portion (Fig. 4-6,A). The ventral portion of the densely arranged cells then migrates laterally and cranially (Fig. 4-6,B). Upon reaching the level of the center of their original somite, these cells spread back to the midline around the notochord. The **dense portion** becomes the future **intervertebral disc**, and the **loosely arranged portion** and the adjacent dense portion left in close juxtaposition combine to become the future **vertebral body** or **centrum** (Fig. 4-6,C). Similarly, the dorsal portion of the sclerotome around the neural tube forms the future **vertebral arch** from its loosely arranged cells, and ligaments from its dense portion. Since the primordia of each vertebra come from two

sclerotomes, they are intersegmental in origin, in contrast to the intervertebral discs, which are segmentally derived. The most ventral extension of the sclerotome forms the future **costal process** from its looser portion and ligaments from the dense portion (Figs. 4-6,B and C; 4-7,A).

This **mesenchymal stage** is succeeded by that of the **cartilaginous vertebral column** (Fig. 4-7). In the sixth week two cartilaginous centers make their appearance, one on each side of the notochord; these extend around the notochord and form the body of the cartilaginous vertebra. A second pair of cartilaginous foci appear more dorsally in the mesenchyme surrounding the neural tube to form the cartilaginous vertebral arch, and a

**Fig. 4-7.** Diagrams illustrating the stages of vertebral development. A, Precartilaginous (mesenchymal) vertebra at five weeks. B, Chondrification centers in a mesenchymal vertebra at six weeks. C, Primary ossification centers in a cartilaginous vertebra at seven weeks. (From Moore, K. L., *The Developing Human*, W. B. Saunders Co., 1973.)

separate cartilaginous center appears for each costal process. Somewhat after the second month the cartilaginous arch has fused with the body, and in the fourth month the two halves of the arch are joined on the dorsal aspect of the neural tube. The spinous process develops from the junction of the two halves of the neural or vertebral arch. The transverse process grows out from the vertebral arch dorsal to the costal process.

In the more cranial cervical vertebrae a band of mesodermal tissue connects vertebral ends of the costal processes, spanning the ventral aspects of the centra and the intervertebral discs. This is termed the **hypochordal bar** or **arch**; in all except the first vertebra, it is transitory and disappears by fusing with the discs. In the atlas, however, the entire bar persists and undergoes chondrification; it develops into the ventral arch of the atlas, while the cartilage representing the body of that bone forms the **dens** or odontoid process, which then fuses with the body of the second cervical vertebra, the **axis**.

The portions of the notochord that are surrounded by the bodies of the vertebrae atrophy, and ultimately disappear, while those that lie in the centers of the intervertebral discs undergo enlargement, and persist throughout life as part of the central **nucleus pulposus** of the discs.

**THE RIBS.** The **ribs** are formed from the ventral or costal processes of the primitive vertebrae which extend between the muscle plates (Fig. 4-6,B and C). In the *thoracic* region of the vertebral column the costal processes grow lateralward to form a series of precartilaginous arches, the **primitive costal**

**arches**. As already described, the transverse process grows out dorsal to the vertebral end of each arch. Initially the transverse process is connected to the costal process by continuous mesoderm, but the interconnecting mesoderm cells become differentiated later to form the costotransverse ligament. Between the costal process and the lateral tip of the transverse process, the costotransverse joint is formed by absorption. The costal process becomes separated from the vertebral centrum by the development of the costocentral joint. In the *cervical* vertebrae (Fig. 4-8) the transverse process forms the posterior boundary of the foramen transversarium, while the costal process, corresponding to the head and neck of a thoracic rib, fuses with the body of the vertebra and forms the anterolateral boundary of the foramen. The distal portions of the primitive costal arches remain undeveloped. Occasionally the arch of the seventh cervical vertebra undergoes greater development, forming an accessory **cervical rib** complete with costovertebral joints. A cervical rib (which may even be bilateral) may compress the trunks of the brachial plexus and the subclavian vessels, resulting in symptoms in the upper extremity. In the *lumbar* region (Fig. 4-8) the distal portions of the primitive costal arches fail to develop, while the proximal portions fuse with the true transverse processes to form the "transverse processes" of descriptive anatomy. Occasionally movable ribs may develop in connection with the first lumbar vertebra. In the *sacral* region costal processes are developed only in connection with the upper three or four vertebrae; the processes of adjacent sacral segments fuse

**FIG. 4-8.** Diagrams showing the portions of the adult vertebrae derived respectively from the bodies (yellow), vertebral arches (red), and costal processes (blue) of the embryonic vertebrae.

with one another to form the lateral masses of the sacrum. The *coccygeal vertebrae* are devoid of costal processes.

**THE STERNUM.** The sternum arises from a pair of mesenchymal bands in the ventrolateral body wall. Although the sternum develops separately from the ribs, on each side the ventral ends of the upper six or seven ribs become joined to these longitudinal bars of mesenchyme, which by this time are called **sternal plates**. These plates become cartilaginous and migrate ventrally toward the midline. The sternal plates of the two sides then fuse in a craniocaudal direction in the midline to form the manubrium and body of the sternum. The xiphoid process is formed by a caudal extension of the sternal plates.

**THE SKULL.** The bones of the skull, like those elsewhere in the body, are derived from mesenchyme. The cranial vault grows around the developing brain and is therefore referred to as the **neurocranium**. Additionally, other bones in the head are derived from the branchial arches and the term **viscerocranium** is applied to these.

The mesenchymal membranes that form the neurocranium in some regions become transformed into bone by endochondral ossification and in other sites by way of intramembranous ossification. Thus, reference is frequently made to the **cartilaginous neurocranium** or **chondrocranium**, which includes the bones at the base of the skull, and the **membranous neurocranium**, which includes certain flat bones of the skull.

The first observable indications of the developing skull are found in the basal occipital and basal sphenoid regions and around the auditory vesicles. Condensation of the primordial mesodermal cells from which the skull will be formed gradually extends from these basal areas completely around the brain until the latter becomes enclosed by a **membranous cranium**, also called the **blastemal skull** or **desmocranium**. The membranous cranium is incomplete in the regions where large nerves and vessels pass into or out of the cranium.

**Cartilaginous Neurocranium.** Before the membranous cranium is even complete, chondrification begins to show in the basilar part of the developing occipital bone (basioccipital). It should be appreciated that chondrification centers develop in relation to the notochord, which extends into the developing cranium from spinal levels (Fig.

**Fig. 4-9.** Sagittal section through the cephalic end of the developing skeleton showing that the notochord extends cranially as high as the basisphenoid. Note that above the atlas the rostral and caudal parts of the notochord become surrounded by the parachordal cartilage, while its middle portion lies between the parachordal cartilage and the wall of the pharynx. (From Gaupp.)

4-9). Two centers appear, one on each side of the notochord near its entrance into the condensed mesoderm of the occipital blastema. Chondrification gradually spreads from these centers—medially around the notochord (**parachordal cartilages**), laterally about the roots of the hypoglossal nerve, and cranialward to unite with the spreading cartilaginous center of the developing basal sphenoid bone (**hypophyseal cartilages**). This process forms an elongated **basal plate** of cartilage extending from the foramen magnum caudally to the cranial end of the sphenoid. It continues into the blastema of the ethmoid region, which later also becomes chondrified (**trabeculae cranii**). Other smaller cartilages lateral to the hypophyseal cartilages unite with the main continuous cartilaginous mass. The **ala orbitalis** (**orbitosphenoid**) forms the lesser wing of the sphenoid bone, and the **ala temporalis** (**alisphenoid**) forms the greater wing of the sphenoid bone (Fig. 4-10). When the auditory capsules begin to chondrify, they are quite widely separated from the basal plate. By the time the embryo is 20 mm in length the cochlear portion of the auditory or otic capsule (**periotic capsule**) is fused to the widened basal plate, and the jugular foramen has become separated from the foramen lacerum (Fig. 4-11). From the lateral region

**FIG. 4-10.** Diagram showing the different components that play a role in the formation of the base of the skull or chondrocranium. (From Langman, Williams and Wilkins, 1975.)

of the occipital cartilage a broad thin plate of cartilage (**tectum posterius** or **nuchal plate**) extends around the caudal region of the brain in a complete ring (Fig. 4-12), forming the primitive foramen magnum. The

complete chondrocranium or cartilaginous neurocranium is shown in Figure 4-12.

Although the chondrocranium forms only a small part of the future ossified skull, it does give rise to most of the base of the skull. Ossification centers then develop in the cartilage and give rise to all of the **occipital bone** (except the upper part of its squama), to the petrous and mastoid portions of the **temporal bone**, to the **sphenoid bone** (except its medial pterygoid plates and part of the temporal wings), and to the **ethmoid bone**.

**Membranous Neurocranium.** The membranous neurocranium consists of those bones of the cranial vault and face which ossify directly in the mesoderm of the membranous cranium. They comprise the upper part of the squama of the occipital bone (interparietal), the squamae and tympanic parts of the temporal bones, the parietal bones, the frontal and vomer bones, the medial pterygoid plates of the sphenoid bone, and the bones of the face. Some membranous bones remain as distinct bones throughout life, e.g., parietal and frontal, while others join with bones of the chondrocranium, e.g., the squama of the occipital, squamae of temporals, and medial pterygoid plates.

**FIG. 4-11.** Cartilaginous skull of 21-mm human embryo. Age of embryo is estimated to be six weeks.

**FIG. 4-12.** Model of the chondrocranium of a human embryo 8 cm long. Its age might be estimated to be 11 weeks. The developing intramembranous bones are not shown. (From Gaupp.)

**Cartilaginous Viscerocranium** (Figs. 4-13; 4-14). Each developing branchial arch has a mesodermal core of mesenchyme covered by an ectodermal exterior and an ectodermal interior. In addition to musculature and blood vessels, the branchial mesoderm develops a skeletal primordium which subsequently chondrifies (Fig. 4-13,A). The dorsal end of the cartilage of the first branchial arch (**Meckel's cartilage**) forms the malleus and also probably the incus of the middle ear, while its intermediate portion forms the anterior malleolar and sphenomandibular ligaments (Fig. 4-13,B). The ventral portion of Meckel's cartilage largely regresses and becomes surrounded by the mesenchyme of the mandible, which then develops by intramembranous ossification. The cartilage of the second branchial arch is called **Reichert's**

**cartilage**. Its dorsal end, directed toward the developing ear, separates to form the stapes of the middle ear. Continuing ventrally it gives rise to the styloid process of the temporal bone (Fig. 4-14), the stylomandibular ligament, and the lesser horn (and probably the upper part of the body) of the hyoid bone (Fig. 4-13,B). The cartilage of the third branchial arch gives rise to the greater horn and the lower part of the body of the hyoid bone. The cartilages of the fourth, fifth, and sixth branchial arches do not ossify but develop as the laryngeal cartilages (Fig. 4-13,B).

**Membranous Viscerocranium.** The remaining skeletal derivatives of the branchial arches develop by intramembranous ossification. From the maxillary process of the first branchial arch, intramembranous ossification of mesenchyme results in the forma-

**FIG. 4-13.** The developing branchial arch cartilage. A, Schematic lateral view of the head and neck region of a four-week embryo, illustrating the location of the branchial arch cartilages. B, Similar view of a 24-week fetus illustrating the derivations of the branchial arch cartilages. (From Moore, K. L., *The Developing Human*, W. B. Saunders Co., 1973.)

tion of the premaxilla, maxilla, and the squama and zygomatic process of the temporal bone. From the mandibular process of the first branchial arch, the mandible develops around the ventral portion of Meckel's cartilage by intramembranous ossification as described (Fig. 4-14). The other branchial arches do not develop bone by intramembranous ossification.

**Axial Skeleton**

The axial skeleton consists of the **vertebral column**, its cranial extension, the **skull**, and the **thoracic cage**, comprised of the sternum and ribs, to which the vertebral column is articulated. In contrast, the term **appendicular skeleton** relates to the bones of the extremities. This central osseous axis of the

body, although flexible in its structure, affords stability and support to the viscera of the head, trunk, and abdomen and allows for the effective locomotor functions of the appended extremities.

### VERTEBRAL COLUMN

The **vertebral column** or **backbone** (*columna vertebralis*; *spinal column*) (Fig. 4-15) is formed by a series of bones called **vertebrae**. The 33 vertebrae are grouped under the names cervical, thoracic, lumbar, sacral, and coccygeal, according to the regions they occupy. There are seven in the cervical region, twelve in the thoracic, five in the lumbar, five in the sacral, and four in the coccygeal.

The cervical, thoracic, and lumbar vertebrae remain distinct throughout life, and are known as **true** or **movable vertebrae**. Those of the sacral and coccygeal regions are termed **false** or **fixed vertebrae**, because they unite or fuse with one another to form two adult bones: five form the sacrum, and four form the terminal bone or coccyx. Between any two adjacent moveable vertebrae (except between the first and second cervical vertebrae) rests a tough, but elastic, fibrocartilaginous intervertebral disc. These intervertebral cushions contribute to the stability of the spinal column because they are strongly bound to the vertebrae, yet they allow considerable movement between the adjoining bones. Furthermore, they allow the spinal column to absorb significant shocks such as those received in jumping from heights or from certain types of exercises and conditioning procedures.

A typical vertebra consists of two essential parts: a ventral segment, the **body**, and a dorsal part, the **vertebral arch** (*arcus vertebralis*; *neural arch*), which encloses the vertebral foramen. Since the bodies of the vertebrae are articulated by the intervertebral discs, they form a strong pillar for the support of the head and trunk, and the vertebral foramina form a longitudinal tube, the vertebral canal, which encloses the spinal cord.

### Vertebral Column as a Whole

The average length of the vertebral column in the male is about 71 cm. Of this length the cervical part measures 12.5 cm,

**FIG. 4-15.** Lateral view of the vertebral column. Observe the cervical, thoracic, lumbar, and pelvic curvatures.

the thoracic about 28 cm, the lumbar 18 cm, and the sacrum and coccyx 12.5 cm. The female column averages about 61 cm in length.

**CURVATURES.** A lateral view (Fig. 4-15) of the vertebral column presents several curves, which correspond with the different regions of the column and are called cervical, thoracic, lumbar, or pelvic. The **cervical curve**, convex ventrally, from the apex of the odontoid process of the axis to the middle of the second thoracic vertebra, is the least marked of all the curves. The **thoracic curve**, concave ventrally, begins at the middle of the second and ends at the middle of the twelfth thoracic vertebra. Its most prominent point dorsally corresponds to the spinous process of the seventh thoracic vertebra. The **lumbar curve** is more marked in the female than in the male; it begins at the middle of the last thoracic vertebra and ends at the sacrovertebral angle. It is convex ventrally, the convexity of the more caudal three vertebrae being much greater than that of the more cranial two. The **pelvic curve** begins at the sacrovertebral articulation, and ends at the point of the coccyx; its concavity is directed caudally and ventrally. The thoracic and pelvic curves are termed **primary curves**, because they alone are present during fetal life. The cervical and lumbar are **compensatory or secondary curves**, and are developed after birth, the former when the child is able to hold up its head (at three or four months) and to sit upright (at nine months), the latter when the child begins to walk (at twelve to eighteen months).

The vertebral column also has a slight **lateral curvature**, the convexity of which is directed toward the right side in right-handed people and toward the left side in individuals who are left-handed. Because of the correlated handedness of the lateral curvature, it is thought by some to be produced by long-continued muscular action. Others, however, believe this curvature to be produced by the aortic arch and upper part of the descending thoracic aorta, a view that is supported by the fact that in cases where the viscera are transposed and the aorta is on the right side, the convexity of the curve is directed to the left side.

**SURFACES.** *Ventral Surface.* Consistent with an increasing weight-bearing function from above downward, the width of the bodies of the vertebrae increases from the second cervical to the first thoracic, diminishes slightly in the next three, then again

progressively increases from the fifth thoracic vertebra as far as the sacrovertebral angle. From this point there is a rapid diminution to the apex of the coccyx.

*Dorsal Surface.* The median line of the dorsal surface of the vertebral column is occupied by the **spinous processes**. In the cervical region (with the exception of the second and seventh vertebrae), these are short and nearly horizontal, with bifid extremities. In the upper part of the thoracic region they are directed obliquely downward; in the mid-thoracic region they are almost vertical; and in the lower thoracic and lumbar regions they are nearly horizontal. The spinous processes are separated by considerable intervals in the lumbar region and by narrower intervals in the neck, but are closely approximated in the middle of the thoracic region. Occasionally one of these processes deviates a little from the median line, a fact to be remembered in practice, as irregularities of this sort are attendant also in fractures or dislocations of the vertebral column. Important clinical landmarks are the protruding spinous processes of the seventh cervical vertebra, which is called the **vertebra prominens**, and that of the first thoracic vertebra, which is virtually as prominent. With the upper extremity in the anatomical position, the inferior angle of the scapula lies at the level of the seventh thoracic spinous process, while the superior border of the iliac crest lies at the plane of the spinous process of the fourth lumbar vertebra.

Lateral to the spinous processes on both sides are longitudinal **vertebral grooves** containing the deep back muscles. In the cervical and lumbar regions these grooves are shallow and they are formed by the laminae of the dorsal arches. In the thoracic region the grooves are deep and broad, and they are formed not only by the laminae but by the transverse processes as well. Lateral to the laminae are the superior and inferior articular processes, and still more laterally the transverse processes. In the thoracic region, the transverse processes are on a plane considerably dorsal to that of the transverse processes in the cervical and lumbar regions. In the cervical region, the transverse processes are placed ventral to the articular processes, lateral to the pedicles, and between the intervertebral foramina. In the thoracic region they are dorsal to the pedicles, intervertebral foramina, and articular processes.

In the lumbar region they are ventral to the articular processes, but dorsal to the intervertebral foramina.

**Lateral Surfaces** (Fig. 4-15). The lateral surfaces are separated from the dorsal surface by the articular processes in the cervical and lumbar regions, and by the transverse processes in the thoracic region. The ventrolateral aspect of the vertebral column is formed by the sides of the bodies of the vertebrae, marked in the thoracic region by the facets for articulation with the heads of the ribs. More dorsally the **intervertebral foramina** are formed by the juxtaposition of the vertebral notches. These foramina are oval in shape, smallest in the cervical and cranial part of the thoracic regions, and gradually increase in size to the last lumbar vertebra. They transmit the spinal nerves and vessels and are situated between the transverse processes in the cervical region, and ventral to them in the thoracic and lumbar regions.

**VERTEBRAL CANAL.** The vertebral canal, which contains the spinal cord, follows the different curves of the column; it is large and triangular in those parts of the column that enjoy the greatest freedom of movement, such as the cervical and lumbar regions; it is small and rounded in the thoracic region, where motion is more limited.

### General Characteristics of a Vertebra

With the exception of the first and second cervical, the true or movable vertebrae have in common certain characteristics that may be studied in a typical vertebra from the

middle of the thoracic region (Fig. 4-16). Characteristically a mid-thoracic vertebra consists of a **body** or **centrum** on its anterior aspect and a **vertebral arch** on its posterior aspect surrounding the **vertebral foramen**, within which lies the spinal cord. The vertebral arch is formed by two **pedicles**, which attach to the vertebral body, and a roof, formed by two **laminae** between which projects the **spinous process** dorsally. Additionally, two superior and two inferior intervertebral **articular processes** stud the pedicles and, dorsolaterally, project the **transverse processes** which, in the thoracic region, afford attachments on each side for the ribs, as do the **costal fovea** on the vertebral body.

The **body** (*corpus vertebrae*; *centrum*) is the largest part of a vertebra, and is nearly cylindrical in shape. On its cranial and caudal surfaces attach the intervertebral discs. These surfaces are rough in the central areas, but a smooth and slightly elevated rim forms their circumference. The surface compact bone ventrally presents a few small apertures for the passage of nutrient blood vessels. The dorsal surface, which faces the vertebral canal, has one or more large, irregular apertures (*foramen vasculare*) for the passage of the basivertebral veins (Fig. 4-17).

The **vertebral arch** (*arcus vertebralis*), which lies posterior to the vertebral body, consists of a pair of pedicles and a pair of laminae which together support seven processes: four articular, two transverse, and one spinous.

The **pedicles** (*pediculi arcus vertebrae*) are two short, thick processes that project dorsally, one on either side, from the cranial

Fig. 4-16. A typical thoracic vertebra, cranial aspect.

**Fig. 4-17.** Sagittal section of a lumbar vertebra showing the foramen vasculare for the passage of the basivertebral vein.

part of the vertebral body at the junction of its dorsal and lateral surfaces (Fig. 4-16). The pedicles are interposed between the transverse processes and the body. They are constricted in the middle, forming the concave **superior** and **inferior vertebral notches** which, when combined in two articulated adjacent vertebrae, form the **intervertebral foramina**.

The **laminae** (*laminae arcus vertebrae*) are two broad plates directed dorsally and medially from the pedicles (Fig. 4-16). They fuse at the midline to complete the dorsal part of the arch surrounding the vertebral foramen and they provide a base for the spinous process. Their superior borders and the caudal parts of their ventral surfaces are rough for the attachment of the ligamenta flava.

**PROCESSES.** The **transverse processes** (*processus transversi*) project laterally on each side from the point where the laminae join the pedicles and between the superior and inferior articular processes (Fig. 4-16). They serve for the attachment of muscles and ligaments.

The **spinous process** (*processus spinosus*) is directed dorsally from the junction of the laminae, and serves for the attachment of muscles and ligaments (Fig. 4-16).

The **articular processes** (*processus articulares*), two superior and two inferior, spring from the vertebral arch at the junctions of the pedicles and laminae. The superior processes project cranially, but their articular surfaces are directed dorsally. The inferior processes are projected caudally and their articular surfaces face ventrally. The articular surfaces are coated with hyaline cartilage and, meeting with those of adjoining vertebrae, form synovial joints.

**STRUCTURE OF A VERTEBRA** (Fig. 4-17). The body is composed of cancellous or spongy bone, covered by a thin coating of compact bone, whereas the arches and processes have a thick covering of compact bone. The interior of the body is traversed by one or two large canals for the basivertebral veins, which converge toward a single large, irregular aperture (*foramen vasculare*) at the dorsal part of the body. The thin bony lamellae of the cancellous tissue are more pronounced in lines perpendicular to the upper and lower surfaces and develop in response to greater pressure from this direction. The dorsal vertebral arch and the processes projecting from it have thick coverings of compact tissue.

### **Cervical Vertebrae**

The **cervical vertebrae** (*vertebrae cervicales*; Figs. 4-12; 4-13) are the smallest of the true vertebrae, and can readily be distinguished from those of the thoracic or lumbar regions by the presence of a foramen in each transverse process. The first, second, and seventh present exceptional features and will be described separately; the following characteristics are common to the remaining four.

The body is small, oval, and broader transversely than dorsoventrally. The ventral and dorsal surfaces are flat and of equal height; the ventral surface is positioned at a slightly lower level than the dorsal and its inferior border is prolonged downward, overlapping the subjacent vertebra in the articulated column (Fig. 4-15). The cranial surface of the cervical vertebral body (Fig. 4-18) is concave transversely, and presents a projecting lip on each lateral aspect; the caudal surface is convex from side to side, and presents shallow concavities laterally which receive the corresponding projecting lips of the subja-

Fig. 4-18. A typical cervical vertebra, cranial view.

cent vertebra. The interlocking nature of the adjacent cervical vertebrae increases the stability of the intervertebral joints. The **pedicles** are attached to the body midway between its cranial and caudal surfaces, so that the superior **vertebral notch** is as deep as the inferior, yet at the same time it is narrower. The **laminae** are narrow and long, and the superior border is thinner than the inferior. The **vertebral foramen** is large and triangular in shape, rather than round. The **spinous process** is short and bifid, the two projections often being of unequal size (Fig. 4-18). The superior and inferior **articular processes** are fused to form an articular pillar (Fig. 4-19), which is situated on the lateral aspect of the junction of the pedicle and lamina. The articular facets are flat and oval: the superior are directed dorsally, cranially, and slightly medially, while the inferior face ventrally, caudally, and slightly laterally.

The **transverse processes** (Fig. 4-18) are each pierced by a **foramen transversarium**, which, in the first six vertebrae, transmits the vertebral artery and vein, accompanied by a plexus of sympathetic nerves. Each transverse process consists of a ventral and a

dorsal part. The portion ventral to the foramen is the homologue of the rib, and is therefore named the *costal process* or *costal element* (see Fig. 4-8). It arises from the side of the vertebral body and ends as the **anterior tubercle**. The dorsal part may be considered the "true" transverse process, homologous to that seen in a thoracic vertebra. It springs from the vertebral arch dorsal to the foramen and is directed ventrally and laterally, ending in a flattened vertical prominence, the **posterior tubercle**. The bar of bone joining the two portions of the transverse process lateral to the foramen exhibits a deep sulcus on its cranial surface for the passage of the corresponding spinal nerve (Fig. 4-19). The costal element of a cervical vertebra includes not only the portion that springs from the side of the vertebral body, but also the anterior and posterior tubercles and the bar of bone that connects them (Fig. 4-8).

The **first cervical vertebra** (Fig. 4-20) is named the **atlas** after a Titan in Greek mythology because it supports the globe of the head. Its chief peculiarity is that it has no vertebral body, and this is because during

Fig. 4-19. Side view of a typical cervical vertebra.

Fig. 4-20. First cervical vertebra, or atlas.

development its centrum fused with that of the second vertebra to form an osseous pivot, the dens (odontoid process) of the axis, which projects superiorly through the atlas and around which the atlas turns. The dens is held in place by the transverse atlantal ligament (see Fig. 4-20). Its other peculiarities are that it has no spinous process, is ring-like, and consists of an anterior and a posterior arch and two lateral masses.

The **anterior arch** forms about one-fifth of the ring; the center of its ventral surface presents the **anterior tubercle** for attachment of the anterior longitudinal ligament and the longus colli muscles. The dorsal or internal surface of the anterior arch is marked by a smooth, oval or circular facet (fovea dentis) for articulation with the dens of the axis. The cranial border gives attachment to the anterior atlanto-occipital membrane which stretches to the occipital bone; along the caudal border of the arch attaches the anterior atlantoaxial ligament which connects it with the axis.

The **posterior arch** forms about two-fifths of the circumference of the ring (Fig. 4-20); it ends dorsally in the **posterior tubercle**, which is the rudiment of a spinous process and gives origin to the two recti capitis posteriores minores. The diminutive size of the spinous process obviates interference with the movements between the atlas and the skull. The cranial surface of the dorsal part of the arch presents a rounded edge for the attachment of the posterior atlanto-occipital membrane. Posterior to each lateral mass, the cranial surface of the posterior arch is marked by a groove (sulcus arteriae vertebralis), which is sometimes converted into a foramen by a delicate bony spicule

growing from the posterior end of the superior articular process. It serves for the transmission of the vertebral artery, which, after ascending through the foramen in the transverse process, winds around the lateral mass in a dorsal and medial direction. Within the groove is also found the suboccipital (first spinal) nerve. Along the caudal surface of the posterior arch, dorsal to the articular facets, are two shallow grooves, the **inferior vertebral notches**, which contribute to the formation of the intervertebral foramina through which pass the second cervical pair of spinal nerves. The inferior border gives attachment to the posterior atlantoaxial ligament.

The **lateral masses** are the most bulky and solid parts of the atlas and support the weight of the head. Each has a superior and an inferior articular facet. The **superior facets** are large, oval, and concave, and converge ventrally. They face cranialward, medialward, and dorsalward, each forming a cup for the corresponding condyle of the occipital bone. At times the superior facets are partially subdivided by indentations that encroach upon their margins. Just inferior to the medial margin of each superior facet is a small tubercle for the attachment of the transverse atlantal ligament, which stretches across the ring of the atlas and divides the vertebral foramen into two unequal parts (Fig. 4-20). The ventral or smaller part receives the dens of the axis, the dorsal transmits the spinal cord and its membranes. This part of the vertebral canal is of considerable size, much greater than is required for the accommodation of the spinal cord, and hence lateral displacement of the atlas may occur as a result of trauma without compres-

sion of the cord. The **inferior articular facets** are circular in form, flattened or slightly convex, and directed caudalward and medialward. They articulate with the axis. The **transverse processes** of the atlas project laterally from the lateral masses, and serve for the attachment of muscles that assist in rotating the head. They are long, their anterior and posterior tubercles are fused into a single mass, and the foramen transversarium is slanted dorsalward (Fig. 4-20).

The **second cervical vertebra** (Figs. 4-21; 4-22) is named the **axis** or **epistropheus** because it forms the pivot upon which the first vertebra, carrying the head, rotates. The axis is the strongest and thickest of the cervical vertebrae. Its most distinctive characteristic is the cranial extension of the body into a strong, tooth-like bony process, the **dens** (odontoid process). The ventral surface of the body is marked by a median ridge for the attachment of the longus colli muscle and is prolonged inferiorly into a lip, which overlaps the third vertebra when articulated.

The **dens** (Figs. 4-21; 4-22), which measures 12 to 15 mm in length, exhibits a slight constriction or neck where it joins the body. Within a shallow groove on the dorsal surface of the neck, which frequently extends onto its lateral surfaces, rests the transverse atlantal ligament. On its ventral surface is an oval or nearly circular facet for articulation with the facet on the anterior arch of the

FIG. 4-21. Second cervical vertebra or axis, cranial aspect.

atlas. The apex of the dens is pointed and gives attachment to the apical dental ligament. Near its junction with the vertebral body, the sides of the dens have rough impressions for the attachment of the alar ligaments, which connect it to the occipital bone. The internal structure of the dens is more compact than that of the body.

The **pedicles** are broad and strong, especially ventrally, where they coalesce with the sides of the vertebral body and the root

FIG. 4-22. Second cervical vertebra, axis or epistropheus, from the side.

of the dens. They are covered cranially by the superior articular surfaces. The **laminae** are thick and strong, and the **vertebral foramen** is large, but smaller than that of the atlas. The small **transverse processes** end in a single tubercle, perforated by the **foramen transversarium**, which is oriented in an obliquely lateral direction. The **superior articular surfaces**, which are oval, slightly convex, and directed cranially and laterally, are supported by the body, pedicles, and transverse processes. They articulate with the inferior articular facets of the atlas. The **inferior articular surfaces** are directed inferiorly and ventrally in a manner similar to that of the other cervical vertebrae (Fig. 4-22). The superior **vertebral notches** are shallow and lie dorsal to the superior articular processes; the inferior lie ventral to the inferior articular processes, as in the other cervical vertebrae. The **spinous process** is large, strong, deeply channeled on its caudal surface, and presents a bifid, tuberculated extremity.

The **seventh cervical vertebra** (Fig. 4-23) is distinguished by its characteristic long and prominent spinous process. This spine, along with that of the first thoracic vertebra, protrudes dorsally beyond the upper six cervical spines in the articulated skeleton, and since it is the most cranial spinous process that is palpable, it is a useful landmark in

**FIG. 4-23.** Seventh cervical vertebra, viewed from above.

identifying and counting the other spines. The seventh cervical vertebra is named, therefore, the **vertebra prominens**. Its spinous process is thick, resembling that of a thoracic vertebra; it is nearly horizontal in direction, not bifurcated, and terminates in a tubercle to which the caudal end of the ligamentum nuchae is attached. The transverse processes are of considerable size, their dorsal components are large and prominent, their ventral, small and faintly marked. The ventral component is derived from the costal element or process (see Fig. 4-8) and may develop into an anomalous cervical rib. The **foramen transversarium** may be as large as that in the other cervical vertebrae, but more usually it is smaller on one or both sides; at times it is double and occasionally it is absent. On the left side it may give passage to the vertebral artery. More frequently, however, the vertebral vein traverses it on both sides. The usual arrangement is for both artery and vein to pass ventral to the transverse process of the seventh cervical vertebra and not through its foramen.

### Thoracic Vertebrae

The **thoracic vertebrae** (*vertebrae thoracicae*; Fig. 4-24) are intermediate in size between the cervical and lumbar, providing a gradual transition from the small cervical cranially to the large lumbar vertebrae caudally. This enlargement of successively more caudal vertebrae may be correlated with the increased weight-bearing requirements of these lower spinal column bones. The thoracic vertebrae are distinguished by the presence of costal facets on the sides of their bodies for articulation with the heads of the ribs, and other articular facets on the transverse processes of the upper ten thoracic vertebrae for articulation with the tubercles of the ribs.

The **bodies** of vertebrae in the mid-thoracic region are heart-shaped, and as broad anteroposteriorly as the transverse diameter. They are flat and slightly thicker dorsally. In fact the ventral length of a thoracic vertebral body measures as much as 2 mm less than its dorsal length, accounting for the thoracic curve of the spinal column (see Fig. 4-15). On the lateral aspect of each thoracic vertebral body are found two **costal demifacets**, one superior near the root of the pedicle, the

Fig. 4-24. A typical thoracic vertebra, right lateral view.

other inferior, ventral to the inferior vertebral notch. In life these articular surfaces are covered with cartilage, and when the vertebrae are articulated in sequence, each two adjacent demifacets form oval surfaces for the reception of the heads of the ribs.

The **pedicles** (Fig. 4-24) are directed dorsally and slightly cranialward from the transverse processes, and the inferior vertebral notches are large and extend more deeply than in any other region of the vertebral column. The **laminae** are broad, thick, and imbricated—that is to say, they overlap those of subjacent vertebrae like tiles on a roof. The **vertebral foramen** is small and circular, and accommodates the narrowed thoracic spinal cord. The **spinous processes** are long, triangular in coronal section, directed obliquely caudalward, and end in tuberculated extremities. The fifth to the eighth thoracic spines are more oblique and overlapping than those of the upper and lower thoracic vertebrae.

The **superior articular processes** (Fig. 4-24) are thin plates of bone that project superiorly from the junctions of the pedicles and laminae. Their articular facets are practically flat, being directed dorsally and a little laterally. The **inferior articular processes** are fused to a considerable extent with the laminae, and project but slightly beyond the inferior borders of the laminae. Their facets are directed ventrally and a little medially

and inferiorly to receive the superior articular processes of subjacent vertebrae. The **transverse processes** arise on each side from the dorsal vertebral arch at the junction of the lamina and the pedicle. These processes are long, thick, and strong and are directed obliquely dorsally and laterally. Each transverse process ends in a clubbed extremity, on the ventral aspect of which is a small, concave surface for articulation with the tubercle of a rib (Fig. 4-24).

The first, ninth, tenth, eleventh, and twelfth thoracic vertebrae present certain peculiarities, and will be considered separately (Fig. 4-25).

The **first thoracic vertebra** has an **entire articular facet** for the head of the first rib and a **demifacet** for the cranial half of the head of the second rib, on each side of the vertebral body. Its centrum is broad transversely like that of a cervical vertebra, which emphasizes the transitional structure of the first thoracic vertebra. The superior articular surfaces are directed cranially and dorsally; the spinous process is thick, long, and almost horizontal. The transverse processes are also long, and each contains an articular facet for the tubercles of the first ribs. The superior vertebral notches are deeper than those of the other thoracic vertebrae.

The **ninth thoracic vertebra**, although otherwise the same as other thoracic vertebrae, may have no demifacets caudally on its

Fig. 4-25. Nontypical thoracic vertebrae.

vertebral body (Fig. 4-25). In some instances, however, two demifacets have been found on each side of the vertebral centrum; when this occurs the tenth vertebral body has demifacets only on its cranial portion.

The **tenth thoracic vertebra** has (except as just mentioned) a single entire articular facet on each side, which also extends partly onto the lateral surface of the pedicle (Fig. 4-25).

The **eleventh thoracic vertebra** has a body that approaches the form and size of the lumbar vertebrae. The articular facets for the heads of the ribs are large and placed chiefly on the pedicles. The pedicles on the

eleventh and twelfth thoracic vertebrae are the thickest and strongest of any in the thoracic portion of the spinal column. The spinous process is short, and nearly horizontal in direction. The transverse processes are very short, tuberculated at their extremities, but have no costal articular facets, since the eleventh pair of ribs articulates only on the lateral aspect of the pedicles.

The **twelfth thoracic vertebra** (Fig. 4-25) has a number of characteristics in common with the eleventh. It may, however, be distinguished from it because (1) its inferior articular surfaces are convex and directed lat-

erally, like those of the lumbar vertebrae, (2) in general form of the body, laminae, and spinous process, it resembles the lumbar vertebrae, and (3) each transverse process is subdivided into three elevations, the **superior, inferior, and lateral tubercles**. The superior and inferior tubercles correspond to the mammillary and accessory processes of the lumbar vertebrae. Less marked but similar elevations are identifiable on the transverse processes of the tenth and eleventh thoracic vertebrae.

### Lumbar Vertebrae

The **lumbar vertebrae** (*vertebrae lumbales*; Figs. 4-26; 4-27) are the largest of the true or moveable vertebrae, a feature that allows them to be distinguished from other vertebrae. Additionally, lumbar vertebrae have no articular facets on the sides of their centra as are found in thoracic vertebrae, and they have no foramina in their transverse processes as are found in cervical vertebrae. The foramen vasculare for the basivertebral vein is larger than in the other vertebrae.

The **body** of a lumbar vertebra is large, wider transversely than dorsoventrally, and a little thicker ventrally than dorsally (Fig. 4-26). It is flat or slightly concave superiorly and inferiorly. The sides of the centrum are concave, so that a finger can easily encircle the circumference of the vertebral body within its grooved concavity. Strong but short **pedicles** unite on the cranial part of the body, leaving deep inferior **vertebral notches** (Fig. 4-26). The **laminae** are broad, short, and strong. The **vertebral foramen** is

triangular, larger than in the thoracic, but smaller than in the cervical region. The **spinous process** is thick, broad, and somewhat quadrilateral in shape and ends in a rough, uneven border, which is thickest caudally where it is occasionally notched. The superior and inferior **articular processes** are well defined, projecting from the junctions of pedicles and laminae (Fig. 4-27). The facets on the superior processes are concave and face dorsally and medially; those on the inferior are convex, and are directed ventrally and laterally. The superior facets are wider apart than the inferior; in the articulated column the inferior articular processes are embraced by the superior processes of the subjacent vertebra. The **transverse processes** are long, slender, and horizontal in the cranial three lumbar vertebrae, but incline a little dorsally in the caudal two. In the upper three vertebrae the transverse processes arise from the junctions of the pedicles and laminae, but in the lower two they are set farther ventrally and spring from the pedicles and dorsal parts of the bodies. Situated ventral to the articular processes instead of dorsal as in the thoracic vertebrae, the transverse processes can be considered homologous with the ribs.

Two additional tubercles found on lumbar vertebrae bear description. On the posterior borders of the large superior articular process are rounded enlargements called the **mammillary processes**, and arising from the dorsal part of the bases of the transverse processes are small rough elevations called the **accessory processes** (Fig. 4-27).

The **fifth lumbar vertebra** (Fig. 4-28) is

FIG. 4-26. A lumbar vertebra, lateral view.

**FIG. 4-27.** A lumbar vertebra, craniodorsal aspect viewed from left.

massive in its structure and its body is much deeper ventrally than dorsally, which accords with the prominent sacrovertebral angle formed at the lumbosacral articulation. The spinous process is smaller than that of other lumbar vertebrae, but the transverse processes are bulky, short, and thick

and arise from the body as well as from the pedicles. The inferior articular processes, which attach to the sacrum, are more widely separated in the fifth lumbar vertebra than in other lumbar vertebrae; the distance approaches or even exceeds that which separates the superior articular processes.

**FIG. 4-28.** Fifth lumbar vertebra, cranial aspect.

**VARIATIONS.** The last lumbar vertebra is subject to certain defects described as *bifid* and *separate neural arches*, the latter occurring three times as frequently as the former. Both defects result from an incomplete union of the bony vertebra and cause weakness in the spinal column: the bifid arch by impairing ligamentous attachments, the separate arch through loss of bony anchorage of the column to its base.

### Sacral and Coccygeal Vertebrae

At an early period of life the sacral and coccygeal vertebrae consist of nine separate segments which, in the adult, are united to form two bones, five entering into the formation of the **sacrum**, four into that of the **coccyx**.

### THE SACRUM (os sacrum)

The **sacrum** is a large, triangular bone, which is situated in the lower part of the vertebral column and forms the dorsal bony wall of the true pelvis (see Fig. 4-191). The broad, superior end of the bone, considered its **base**, articulates with the last lumbar vertebra, while its more narrow apex articu-

lates inferiorly with the coccyx. Inserted like a wedge between the two hip bones, its base projects ventrally and forms the prominent **sacrovertebral angle** when articulated with the last lumbar vertebra. Its central part is projected dorsally (see Fig. 4-190). It encases the sacral canal within which course the sacral nerves.

The **pelvic surface** (*facies pelvina*; Fig. 4-29) is concave, giving increased capacity to the pelvic cavity. Its median part is crossed by four **transverse ridges**, the positions of which correspond to the original planes of separation between the five segments of the fetal bone (see Fig. 4-44). The four ridges represent the intervertebral discs of the immature sacrum which then ossified and fused. Intervening between the ridges are the **bodies** of the sacral vertebrae. The body of the first segment is large, and in form resembles that of a lumbar vertebra. Succeeding ones diminish in size, are flat and curve with the form of the whole sacrum. Four pairs of rounded **pelvic sacral foramina** are located at the ends of the transverse ridges. These foramina communicate with the sacral canal by means of intervertebral foram-

FIG. 4-29. Sacrum, pelvic surface.

**FIG. 4-31.** Lateral aspect of sacrum and coccyx.

ward as rounded processes named the **sacral cornua**, which are connected to the cornua of the coccyx (Fig. 4-30). Lateral to the intermediate crest are the four **posterior sacral foramina** (Fig. 4-30). Smaller in size and less regular in form than the ventral foramina, they transmit the dorsal divisions of the sacral nerves. Lateral to the dorsal foramina, a series of tubercles represents the **transverse processes** of the sacral vertebrae and forms the **lateral crests** of the sacrum (Fig. 4-31). The tubercles of the first and second sacral segments receive the attachment of the horizontal parts of the posterior sacroiliac ligaments; those of the third vertebra give attachment to the oblique fasciculi of the dorsal sacroiliac ligaments; and those of the fourth and fifth to the sacrotuberous ligaments.

The lateral surface (Fig. 4-31) of the sac-

rum is broad and irregular cranially, narrow caudally, and formed by the union of elements comparable to the costal and transverse processes seen in other vertebrae (Fig. 4-32). The upper half of this surface presents a large ear-shaped articular facet, the **auricular surface**, which is covered with cartilage in the fresh state for articulation with the ilium. Dorsal to it is a rough surface, the **sacral tuberosity** (Fig. 4-31), on which are three deep and uneven impressions for the attachment of the posterior sacroiliac ligament. The caudal half of the lateral surface is thin and ends in a projection called the **inferior lateral angle** (Fig. 4-30); medial to this angle is a notch that is converted by the transverse process of the first coccygeal segment into a foramen for transmission of the ventral division of the fifth sacral nerve. The thin caudal half of the lateral surface gives attachment

**FIG. 4-32.** Base of sacrum. This superior end of the sacrum articulates with the fifth lumbar vertebra.

to the sacrotuberous and sacrospinous ligaments, to some fibers of the gluteus maximus muscle, and to the coccygeus muscle.

The **base of the sacrum** (*basis ossis sacri*; Fig. 4-32), which is its cranial surface, is broad and expanded laterally. In its center is the upper surface of the **body** of the first sacral vertebra. The ventral border of the body projects into the pelvis as the **promontory**. The articulation between the body of the first sacral segment and the body of the fifth lumbar vertebra is interposed by an intervertebral disc. The orifice of the **sacral canal** lies dorsal to this articulation. As is seen throughout the vertebral column, the sacral canal is completed dorsally by the laminae and spinous process. The superior articular processes on either side are directed dorso-medially, as are the superior articular processes of a lumbar vertebra. They are attached to the body of the first sacral vertebra and to the wings, or **alae**, by short thick pedicles. On the cranial surfaces of each pedicle is a vertebral notch that forms the caudal part of the intervertebral foramen between the last lumbar and the first sacral vertebrae. On either side of the body, a large triangular surface called the **ala** supports the psoas major muscle and the lumbosacral nerve trunk, and receives the attachment of a few fibers of the iliacus muscle. The dorsal quarter of the ala represents the transverse process, and its ventral three-quarters the costal process of the first sacral segment (Fig. 4-32).

The **apex** (*apex ossis sacri*) is the caudal extremity of the sacrum and presents an oval facet for articulation with the coccyx.

The **sacral canal** (*canalis sacralis*; Figs.

4-26; 4-27), the vertebral canal in the sacrum, is incomplete inferiorly due to the nondevelopment of the laminae and spinous processes of the last one or two segments. The resultant widened aperture into the caudal end of the sacral canal, the **sacral hiatus** (Fig. 4-30), is used by anesthesiologists for the insertion of a flexible needle to produce caudal analgesia. The canal lodges the sacral nerves of the lower spinal cord's cauda equina, and its walls are perforated by the dorsal and ventral sacral foramina through which these nerves pass.

**STRUCTURE.** The sacrum consists of cancellous bone enveloped by a thin layer of compact bone. In a sagittal section through the center of the sacrum (Fig. 4-33), the bodies appear united at their circumferences by bone, but in the center are wide intervals which, in the intact body, are filled by the intervertebral discs. This union may be more completely ossified between the caudal segments than between the cranial segments in some sacra.

**ARTICULATIONS.** The sacrum articulates with four bones: the last lumbar vertebra cranially, the coccyx caudally, and the hip bone on each side.

**DIFFERENCES IN THE SACRUM OF THE MALE AND THE FEMALE.** The wider female pelvic cavity is partially explained by the fact that the female sacrum is shorter and wider than the male. The cranial half of the sacrum is nearly straight while the caudal half presents a curvature. In women the caudal half forms a greater angle with the cranial half. The female sacrum being more oblique and dorsally directed renders the sacrovertebral angle more prominent. In the male the curvature of the sacrum is more evenly distributed over the whole length of the bone.

**VARIATION.** The sacrum may consist of the remnants of six segments, in which case a part of the

FIG. 4-33. Median sagittal section of the sacrum.

last lumbar or first coccygeal vertebra is included (sacralization). More occasionally the number is reduced to four. The bodies of the first and second may fail to unite. Sometimes the uppermost transverse tubercles are not joined to the rest of the ala on one or both sides, or the sacral canal may be open throughout a considerable part of its length in consequence of the imperfect development of the laminae and spinous processes. The sacrum also varies considerably with respect to its degree of curvature.

### THE COCCYX (os coccygis)

Usually formed of four rudimentary vertebrae, the coccyx (Figs. 4-34; 4-35) may consist of three or as many as five segments. This small triangular bone articulates superiorly with the apex of the sacrum, and its inferior tip is the lowest part of the spinal column. Rudimentary bodies and articular and transverse processes can be identified in the first three segments, but coccygeal vertebrae are destitute of pedicles, laminae, and spinous processes. The first segment is the largest, and, resembling the last sacral vertebra, it

often exists as a separate bone. The lowest three segments diminish in size, and are usually fused with one another. Of these, the last segment is a mere module of bone.

The **pelvic surface** is marked with three transverse grooves, which indicate the junctions of the different segments. It gives attachment to the ventral sacrococcygeal ligament, and to its lateral margins are inserted muscle fibers of the coccygeus and levator ani muscles. Additionally, it is in contact with a part of the rectum. The **dorsal surface** has a row of tubercles on both sides; these are the rudimentary articular processes. The large first pair of tubercles is called the **coccygeal cornua**; it articulates with the cornua of the sacrum, and on each side completes the intervertebral foramen for the transmission of the dorsal division of the fifth sacral nerve.

On the **lateral borders** of the coccyx a series of small eminences represents the transverse processes. The uppermost pair is the largest, and on each side the transverse proc-

FIG. 4-34. Coccyx, pelvic surface.

FIG. 4-35. Coccyx, dorsal surface.

ess often joins the thin lateral edge of the sacrum, thus completing the foramen for the transmission of the ventral division of the fifth sacral nerve. The narrow borders of the coccyx receive the attachments of the sacrotuberous and sacrospinous ligaments laterally, the coccygeus muscle and the ilio-coccygeal portion of the levator ani muscle ventrally, and the origin of the gluteus maximus muscle dorsally. The oval facet on the surface of the base articulates with the sacrum. The rounded apex may be bifid, or deflected to one side, and has the tendon of the sphincter ani externus attached to it.

### **Variations and Anomalies of the Vertebral Column**

**NUMBER OF VERTEBRAE.** Variation in the total number of vertebrae cranial to the coccyx is less common than variations in the normal number within the different regions. The number of segments in the coccyx is the most variable, the sacral next, then the thorax, and finally variation in the number of cervical vertebrae the least common. The number of vertebrae in one region may be increased at the expense of the number in a neighboring region however. Variations in the lumbosacral and cervicothoracic region are rather frequent and usually can be traced to anomalies in the development of the costal processes (Fig. 4-8). The **costal processes** of the twelfth thoracic vertebra may be wanting, in which case there will be eleven thoracic and six lumbar vertebrae. Conversely, the costal element of the first lumbar may develop into a rib, resulting in thirteen thoracic and four lumbar vertebrae. The costal element of the last lumbar may unite with the first sacral, a condition known as *sacralization of the lumbar vertebra*, resulting in four lumbar and six sacral segments. True sacralization does not take place, however, unless the fifth lumbar enters into the articulation with the ilium. Again, the first sacral segment may fail to unite with the other sacrals, resulting in six lumbar and four sacral segments. There may be a secondary sacral promontory.

**CERVICAL RIB.** Occasionally a cervical rib condition develops in which the costal element of the seventh cervical is elongated into a separate rib-like structure. In rare instances, such a rib may be long enough to articulate with the sternum. This anomaly may cause interference with blood flow in the subclavian artery or paralysis in the upper extremity due to pressure on the brachial plexus.

**ASYMMETRY.** One side of a vertebra may develop defectively to a greater or lesser degree. When this occurs on one side of the centrum or body, the resulting condition is called *congenital scoliosis* or lateral curvature. In other situations an overgrowth or failure of the costal process may occur on one side,

especially in the lumbosacral region, or there may exist one-sided defects in the pedicles and laminae.

**SPINA BIFIDA.** At times laminae fail to unite and form a spinous process. Not uncommonly it involves only one or two vertebrae and causes few symptoms (*spina bifida occulta*). Depending on the size of the defect, there may be a small fat pad or lipoma in its place, but larger defects may contain a *meningocele* or a *myelomeningocele* produced by fluid and the protrusion of tissues from the spinal canal. The most common site of spina bifida is the lumbar region, less common is the cervical region. In some instances the absence of spinous processes may extend distally through the entire sacrum, leaving the sacral canal exposed. Other parts of the neural arch may have similar defects. The union of the pedicles with the body may fail on one or both sides; the resulting weakness of the arch may cause displacement of one vertebra over the other, the condition named *spondylolisthesis*.

### **Ossification of the Vertebral Column**

Each cartilaginous vertebra is ossified from **three primary centers** (Fig. 4-36), two for the vertebral arch and one for the body. Ossification of the vertebral arches begins in the upper cervical vertebrae during the seventh or eighth week of fetal life, and gradually extends to more caudal vertebrae. The ossific granules first appear at the sites from which the transverse processes eventually project. Ossification spreads dorsally to the spinous process, ventrally into the pedicles, and laterally into the transverse and articular processes. Ossification of the vertebral bodies begins about the eighth week in the lower thoracic region, and subsequently extends cranially and caudally along the column. The initial ossification center for the body does not give rise to the entire centrum of the adult vertebra, since the dorsolateral portions are ossified by extensions from the vertebral arch. During the first few years of life the body of a vertebra, therefore, shows two lines of union of the neural arch with the centrum. These sites of junction are called **neurocentral synchondroses** (Fig. 4-37). In the thoracic region, the facets for the heads of the ribs lie dorsal to the neurocentral synchondroses and are ossified from the centers for the vertebral arch.

At birth the vertebra consists of three parts, the body and the two halves of the vertebral arch joined by cartilage. During the first year the halves of the arch unite dorsally, union taking place first in the lumbar region and then extending cranially through the thoracic and cervical regions. About the third year the bodies of the upper cervical vertebrae are joined to the arches on each side, but this union in the caudal lumbar vertebrae is not completed until the sixth year. During the years before puberty these primary ossification centers gradually increase in size, while the cranial and caudal surfaces of the bodies and the ends of the transverse and spinous

## THREE PRIMARY CENTERS

FIG. 4-36.

## FIVE SECONDARY CENTERS

FIG. 4-37.

FIG. 4-38.

**Figs. 4-36 to 4-38.** Ossification of a vertebra. Fig. 4-36. The three primary ossification centers are indicated. Fig. 4-37. Three secondary centers, to which are added two other secondary centers on the upper and lower surfaces of the vertebral body (Fig. 4-38).

processes remain cartilaginous. About the sixteenth year (Fig. 4-37), **five secondary centers** appear, one for the tip of each transverse process, one for the extremity of the spinous process, one for the cranial and one for the caudal surface of the body (Fig. 4-38). The secondary centers fuse with the rest of the bone about the age of twenty-five.

The mode of ossification just described occurs in vertebrae of the spinal column from the third through the sixth cervical and the twelve thoracic segments. Exceptions to this ossification pattern, however, occur in the first, second, and seventh cervical vertebrae, and in the lumbar, sacral, and coccygeal vertebrae.

**ATLAS.** The atlas is usually ossified from three centers (Fig. 4-39). Two of these usually appear in the lateral masses during the seventh week of fetal life. At birth, the dorsal portions of bone are separated from one another by a narrow interval filled

## THREE OSSIFICATION CENTERS

**FIG. 4-39.** Ossification centers in the atlas (first cervical vertebra).

with cartilage. Between the third and fourth years the posterior arch becomes united either directly or through the development of a separate ossification center in the cartilage. The anterior arch consists of cartilage at birth; a separate center appears toward the end of the first year after birth and eventually joins the lateral masses between the sixth and eighth years. The lines of this union extend across the ventral portions of the superior articular facets (Fig. 4-39). Occasionally there is no separate center for the ventral arch, or it may ossify from two centers, one on each side of the midline.

**AXIS OR EPISTROPHEUS.** The axis ossifies from five primary and two secondary centers (Fig. 4-40). The body and arch are ossified in the same manner as in the other vertebrae, i.e., one primary center for the body, and two for the vertebral arch. The centers for the arch appear about the seventh or eighth week of fetal life, that for the body about the fourth or fifth month. The **dens** (being the representation of the body of the atlas) commences ossification during the sixth fetal month from two laterally placed primary centers in its base. These two centers join before birth and form a conical mass of bone which has a cleft superiorly. The interval between the sides of the cleft is filled by a wedge-shaped piece of cartilage, thereby forming the summit of the process. This cartilaginous apex of the dens has a separate secondary ossification center which appears during the second year and joins the main part of the process about the twelfth year. The base of the dens is separated from the vertebral body by a cartilaginous disc, which gradually becomes ossified at its circumference, but remains cartilaginous in its center until advanced age. In this cartilage, rudiments of the caudal epiphyseal lamella of the atlas and the cranial epiphyseal lamella of the axis may sometimes be found. Additionally, there is a secondary center for a thin epiphyseal plate on the caudal surface of the body of the bone which ossifies at about the seventeenth year.

**SEVENTH CERVICAL VERTEBRA.** In addition to the ossification centers described for typical cervical and thoracic vertebrae, the ventral or costal part of the transverse processes of the seventh cervical vertebra is sometimes ossified from separate centers which appear about the sixth month of fetal life. These generally join the body and dorsal part of the transverse process between the fifth and sixth years. They may continue to grow laterally as cervical ribs.

## SEVEN OSSIFICATION CENTERS

**Fig. 4-40.** Ossification centers in the axis (second cervical vertebra).

**LUMBAR VERTEBRAE.** Each lumbar vertebra (Fig. 4-41) has two additional ossification centers for the mammillary processes, as well as those described for typical cervical and thoracic vertebrae. Similar to those in the transverse and spinous processes, the mammillary processes ossify at about the seveneenth year. The transverse process of the first lumbar is sometimes developed separately, and may remain permanently apart from the rest of the bone, thus forming a rare peculiarity, a lumbar rib.

**THE SACRUM** (Figs. 4-42 to 4-45). The body of each sacral vertebra is ossified from a primary center and two epiphyseal plates, while each vertebral arch becomes ossified from two centers. Cranial and lateral to the pelvic foramina, six or more additional ossification centers develop, two (one on each side) for each of the upper three or four sacral vertebrae. These represent the costal elements of the sacral segments (Figs. 4-42; 4-43). On the cranial and caudal surfaces of each sacral vertebral body, ossification centers for the epiphyseal plates develop (Fig. 4-44). Further, on each lateral surface two epiphyseal plates are formed (Figs. 4-44; 4-45): one for the auricular surface, and another for the remaining lower part of the thin lateral edge of the bone.

About the eighth or ninth week of fetal life, ossification of the central part of the body of the first sacral vertebra commences; similarly, ossification rapidly follows in the second and third. Ossification does not commence in the bodies of the last two sacral segments until the fifth to eighth month of fetal life. Between the sixth and eighth months ossification of the vertebral arches occurs, and at about the same time the costal centers make their appearance laterally. The vertebral arches join with the

**Fig. 4-41.** Ossification centers in lumbar vertebrae include an additional two secondary centers for the mammillary processes.

**Fig. 4-42.** The sacrum at birth shows ossification not only in the five centra, but also in the costal elements on each side of the upper three or four sacral vertebrae (marked by asterisks).

**Fig. 4-43.** By 4½ years, the ossified lateral sacral processes have joined the centra, but the lateral epiphyseal plates and those between the bodies are still cartilaginous.

**Fig. 4-44.** By the twenty-fifth year, ossification centers have appeared not only in the intervertebral epiphyseal plates, but in those bordering the lateral margins of the sacrum (marked by asterisks).

**Fig. 4-45.** Base of the sacrum in a child of four to five years (viewed from above).

bodies in the more caudal vertebrae as early as the second year, whereas this does not occur in the more cranial until the fifth or sixth year. About the sixteenth year the epiphyseal plates for the superior and inferior surfaces of the bodies are formed; and between the eighteenth and twentieth years, those for the lateral surfaces make their appearance. During early life the bodies of the sacral vertebrae are separated from each other by intervertebral discs, but by about the eighteenth year the last two segments become united by bone, and the process of bony union gradually extends cranially. Between the twenty-fifth and thirtieth years of life all the sacral segments are united intervertebrally.

**THE COCCYX.** The coccyx is ossified from four primary centers, one for each segment. These centers make their appearance soon after birth in the first segment and between the fifth and tenth years in the second segment. Ossification of the third segment commences before puberty (between the tenth and fifteenth years), and after puberty in the fourth segment (between the fourteenth and twentieth years). As age advances, the segments unite intervertebrally. The union between the first and second segments is frequently delayed until after the age of twenty-five or thirty. At a late period of life, especially in women, the coccyx often fuses with the sacrum.

## THE THORAX

The skeleton of the **thorax** or **chest** (Figs. 4-46 to 4-48) forms an osseocartilaginous cage which protects the principal organs of respiration and circulation. It extends inferiorly over the upper part of the abdomen, thereby covering portions of certain abdominal organs. It is conical in shape, so that its superior or cervical inlet is of lesser diameter than its inferior abdominal end. In transverse section it appears kidney-shaped because of the projection of the vertebral bodies into the cavity. The thoracic cage is formed by the ribs with their costal cartilages attached anteriorly to the sternum (Fig. 4-46) and posteriorly to the thoracic vertebrae of the spinal column (Fig. 4-48).

**BOUNDARIES.** The **dorsal surface** is formed by the twelve thoracic vertebrae and the dorsal parts of the twelve ribs. The **ventral surface** is formed by the sternum and costal cartilages. The **lateral surfaces** are formed by the ribs, separated from each other by the eleven intercostal spaces within which are located the intercostal muscles and membranes.

The **superior opening** of the thoracic cage is broader from side to side than dorsoven-

trally. It is formed by the first thoracic vertebra, the cranial margin of the sternum, and the first rib on each side. Its dorsoventral diameter is about 5 cm, and its transverse diameter about 10 cm. The plane of the aperture slopes caudally from the spinal column toward the sternum, since the upper border of the sternum lies 3 to 5 cm below the upper border of the body of the first thoracic vertebra. Thus, the thoracic inlet faces ventralward as well as cranialward (Figs. 4-46; 4-48).

The **inferior opening** or thoracic outlet is formed dorsally by the twelfth thoracic vertebra, laterally by the eleventh and twelfth ribs, and ventrally by the cartilages of the tenth, ninth, eighth, and seventh ribs, which slope on each side to form the **infrasternal angle** at the xiphoid process. This caudal opening, also wider transversely than dorsoventrally, inclines obliquely caudalward and dorsalward. It is closed by the diaphragm, which forms both the floor of the thorax and the roof of the abdomen.

The thorax of the female differs from that of the male as follows: (1) its capacity is less; (2) the sternum is shorter; (3) the cranial margin of the sternum is on a level with the caudal part of the body of the third thoracic vertebra, whereas in the male it is on a level with the caudal part of the body of the second; and (4) the upper ribs are more movable, permitting a greater expansion of the cranial part of the thorax.

## The Sternum

The **sternum** (Figs. 4-49 to 4-53) is an elongated, flat bone, which forms the middle portion of the ventral wall of the thorax. Its cranial end supports the clavicles, and its lateral margins articulate with the cartilages of the first seven pairs of ribs. The adult sternum consists of three parts, the **manubrium**, the **body**, and the **xiphoid process**. In early life, the sternum consists of six segments. The first and sixth remain as separate parts, the manubrium and xiphoid process respectively, while the intermediate four segments or **sternebrae** fuse to become the sternal body. The sternum is broad superiorly where the first ribs attach and in the region of the body where the fourth and fifth ribs attach. It narrows at the junction of the manubrium with the body, where the second ribs articulate, and once again at its inferior extremity (Fig. 4-49). In its natural position, the sternum is directed inferiorly, the caudal

**FIG. 4-46.** The ventral aspect of the thoracic cage. Observe that all 12 pairs of ribs articulate with their respective thoracic vertebrae; however, only the first seven pairs attach directly to the sternum. The eighth and ninth ribs attach to the cartilage of the seventh rib on each side, while the tenth, eleventh and twelfth pairs have no anterior articulation. (From Spalteholz.)

end of the bone being inclined somewhat anteriorly and away from the vertebral column. Its average length in the adult is about 17 cm, being rather longer in males than in females. Projected posteriorly onto the vertebral column, the manubrium lies at the level of the third and fourth thoracic vertebrae. Its articulation with the sternal body is level with the intervertebral disc between the fourth and fifth vertebrae. The body of the sternum lies anterior to the fifth to tenth thoracic vertebrae. A line from the xiphoid process projects back to the eleventh thoracic vertebra.

The **manubrium** (*manubrium sterni*) is quadrangular in shape, broad and thick

cranially, but more narrow caudally at its junction with the body.

Its **ventral surface** is smooth, and on each side affords attachment to the pectoralis major and sternocleidomastoideus muscles (Fig. 4-49). The ridges limiting the attachments of these muscles are at times quite distinct. Its **dorsal surface**, concave and smooth, affords attachment on each side to the sternohyoid and sternothyroid muscles (Fig. 4-50).

The **cranial border** of the manubrium is thick and presents at its center the **jugular** (suprasternal) **notch**, on each side of which, at the **clavicular notch**, is an oval articular surface for the sternal end of the clavicle.

**FIG. 4-47.** The dorsal aspect of the thoracic cage. Note that each rib articulates with its respective thoracic vertebra, and upon encircling the trunk in an inferolateral direction, articulates anteriorly at a site lower than its vertebral commencement. Thus, any respective intercostal space lies higher dorsally than ventrally. (From Spalteholz.)

The **caudal border**, oval and rough, is surfaced by a thin layer of cartilage for articulation with the body. The upper aspect of the **lateral borders** is marked by a depression for the first costal cartilage. Found caudally is a small facet that forms part of the notch for the reception of the costal cartilage of the second rib.

The **body** (*corpus sterni*) of the sternum is considerably longer, narrower, and thinner than the manubrium. Its **ventral surface** is nearly flat and is marked by three transverse ridges which cross the bone opposite the third, fourth, and fifth costal articular depressions. These ridges define the sites of ossification of the original four sternbrae.

This anterior surface affords attachment on each side to the sternal origin of the pectoralis major, the line of origin of this muscle continuing down from the manubrium. At the junction of the third and fourth sternbrae of the body, a sternal foramen of varying size and form is occasionally seen. The slightly concave **dorsal or internal surface** is also marked by three transverse lines, less distinct, however, than the ventral; from its caudal part, the transversus thoracis muscle takes origin on each side (Fig. 4-50).

The **cranial border** of the sternal body is oval and articulates with the manubrium, the junction of the two forming the **sternal angle** (*angle of Louis*). The **caudal border** is

**FIG. 4-48.** The thoracic cage viewed from the right side. Observe that the lateral wall of the thorax is supported by the bodies of the ribs. Note that the ribs initially course in an inferolateral direction from the vertebral column and then inferomedially to achieve the costal cartilages and the sternum. (From Spalteholz.)

narrow, and articulates with the xiphoid process. Each **lateral border** (Fig. 4-51), at its cranial end, has a small facet which, with a similar facet on the manubrium, forms a cavity for the cartilage of the second rib. Caudal to this are found four angular depressions which receive the cartilages of the third, fourth, fifth, and sixth ribs. At its caudal end the sternal body has a small facet, which combines with a corresponding one on the xiphoid process to form a notch for the cartilage of the seventh rib. These articular depressions are separated by a series of curved interarticular intervals, which diminish in length caudally, and correspond to the ventral extremities of the intercostal spaces. Most of the costal cartilages extend-

ing from the true ribs articulate with the sternum at the lines of junction of its primitive component sternbrae segments. This is frequently seen even more clearly in many lower animals, in which the sternbrae remain distinct longer than in man.

The **xiphoid process** (*processus xiphoideus*) is the smallest of the three parts of the sternum. It is thin and elongated, cartilaginous in youth, but more or less ossified proximally in the adult. Its **ventral surface** affords attachment on each side to the ventral costoxiphoid ligament and to a small part of the rectus abdominis muscle. Onto the **dorsal surface** are attached the dorsal costoxiphoid ligament and some of the fibers of the diaphragm and the transversus thoracis

**FIG. 4-49.** The anterior surface of the sternum and ribs. Observe the costal cartilages and their manner of articulation with the sternum. Suprasternally note the jugular notch on the superior border of the manubrium, lateral to which articulate the clavicles. The infrasternal angle is formed by the midline articulation of the costal margins of the two sides. Muscle origins are in red, insertions in blue.

muscles. The **lateral borders** give attachment to some fibers of the aponeuroses of the abdominal muscles.

The xiphoid process articulates with the sternal body, and at each superior angle presents a facet for part of the cartilage of the seventh rib. The pointed caudal extremity gives attachment to the linea alba. The xiphoid process varies much in form; it may be broad and thin, pointed, bifid, perforated, curved, or deflected considerably to one side or the other.

**STRUCTURE.** The sternum is composed of highly vascular cancellous bone, covered by a thin, compact layer which is thickest in the manubrium between the articular facets for the clavicles. When necessary, the sternum is utilized by hematologists for *sternal puncture*, in which a needle of large bore is thrust through the thin subcutaneous cortical bone and a specimen of red marrow aspirated.

**OSSIFICATION.** The sternum early appears as two cartilaginous bars, situated one on each side of the median plane. Each of these two sternal plates is connected with the cartilages of the upper nine ribs of its own side. The two bars then fuse along the midline to form the cartilaginous sternum, which is subsequently ossified from six centers: one for the manubrium, four for the body, and one for the xiphoid process (Fig. 4-52). The ossification centers appear in the intervals between the articular depressions for the costal cartilages, in the following order: in the manubrium and first piece of the body during the sixth prenatal month; in the second and third sternbrae of the body during the seventh month of fetal life; in the fourth sternbrae of the body during the first year after birth; and in the xiphoid process between the fifth and eighteenth years. As a rule, ossification commences in the more superior parts of the segments and proceeds caudalward. Occasionally two additional small episternal centers may develop on each side of the jugular notch. These are probably vestiges of the episternal bone of the monotremes and lizards.

**FIG. 4-50.** Dorsal surface of the sternum. Observe the transverse lines of union between the segments of the sternal body. Note also the attachments of the sternohyoid and sternothyroid muscles on the manubrium and the diaphragm and transverse thoracis muscles inferiorly.

Multiple ossification centers within the sternal segments are frequently encountered, the number and position of which vary. Thus, manubrium may develop from two, three, or even six centers. When two are present, they are generally situated one superior to the other, the cranial being the larger. The second piece seldom has more than one center, while the third, fourth, and fifth pieces are often formed from two laterally placed centers, the irregular union of which explains the rare occurrence of a sternal foramen. The imperfect union of the longitudinally oriented cartilaginous bars may result in a vertical fissure constituting the malformation known as *fissura sterni*. This condition is seen more frequently lower in the sternum, but may occur even in the manubrium. If extensive, pulsations of the heart may be readily observed through the skin of the anterior chest wall.

Union of the four segments of the sternal body commences at puberty and proceeds cranially from the lower segments (Fig. 4-53). By the age of twenty-five the segments of the sternal body are all united. The xiphoid process may become ossified to the sternal body before the age of thirty, but this occurs more frequently after forty; at times the xiphisternal junction remains ununited in old age. In advanced life the manubrium may occasionally be joined to the body by bone. When this happens,

however, the bony tissue is usually superficial, and the central portion of the intervening cartilage remains unossified.

**ARTICULATIONS.** The sternum articulates on each side with the clavicle and first seven costal cartilages.

### The Ribs

The ribs (costae) are flattened, narrowed, elastic arches of bone, which form a large part of the thoracic skeleton. There are usually twelve pairs. The first seven pairs, called **true or vertebrosteral ribs**, are connected dorsally with the vertebral column, and ventrally by means of costal cartilages, with the sternum (Figs. 4-46 to 4-49). The remaining five pairs are false ribs and consist of two types: the eighth, ninth, and tenth have their cartilages attached to the cartilage of the rib above (**vertebrochondral**), while the eleventh and twelfth are free at their ventral extremities and termed **floating or vertebral ribs**, since they do not attach to the sternum.

**FIG. 4-51.** Lateral border of the sternum. Observe that the facets for the second costal cartilages lie laterally at the junction of the manubrium and sternal body, while the facets for the seventh cartilages lie laterally at the xiphisternal junction.

**Fig. 4-52.** Ossification centers for the sternum and their times of appearance. Multiple centers are frequently seen in certain of the segments.

The ribs vary somewhat in their shape and direction, the upper ones being less oblique, and curving at a more acute angle than the lower. The obliquity reaches its maximum at the ninth rib, and gradually decreases again from that rib to the twelfth. The ribs are arranged in a serial manner below one another, each being separated from the next by intercostal spaces. The length of each space around the thorax corresponds to that of the adjacent ribs and their cartilages. The breadth of the intercostal spaces is greater ventrally than dorsally and greater between the more superior ribs than between the lower ones. The ribs increase in length from the first to the seventh, then diminish to the twelfth.

**CHARACTERISTICS OF THE RIBS** (Figs. 4-54; 4-55). A rib from the middle of the series may be used to study the common characteristics of these bones. Each rib has two extremities, a dorsal or vertebral, and a ventral or sternal. The intervening portion is called the body or shaft.

**Fig. 4-53.** Times when ossified union occurs between the six segments of the sternum.

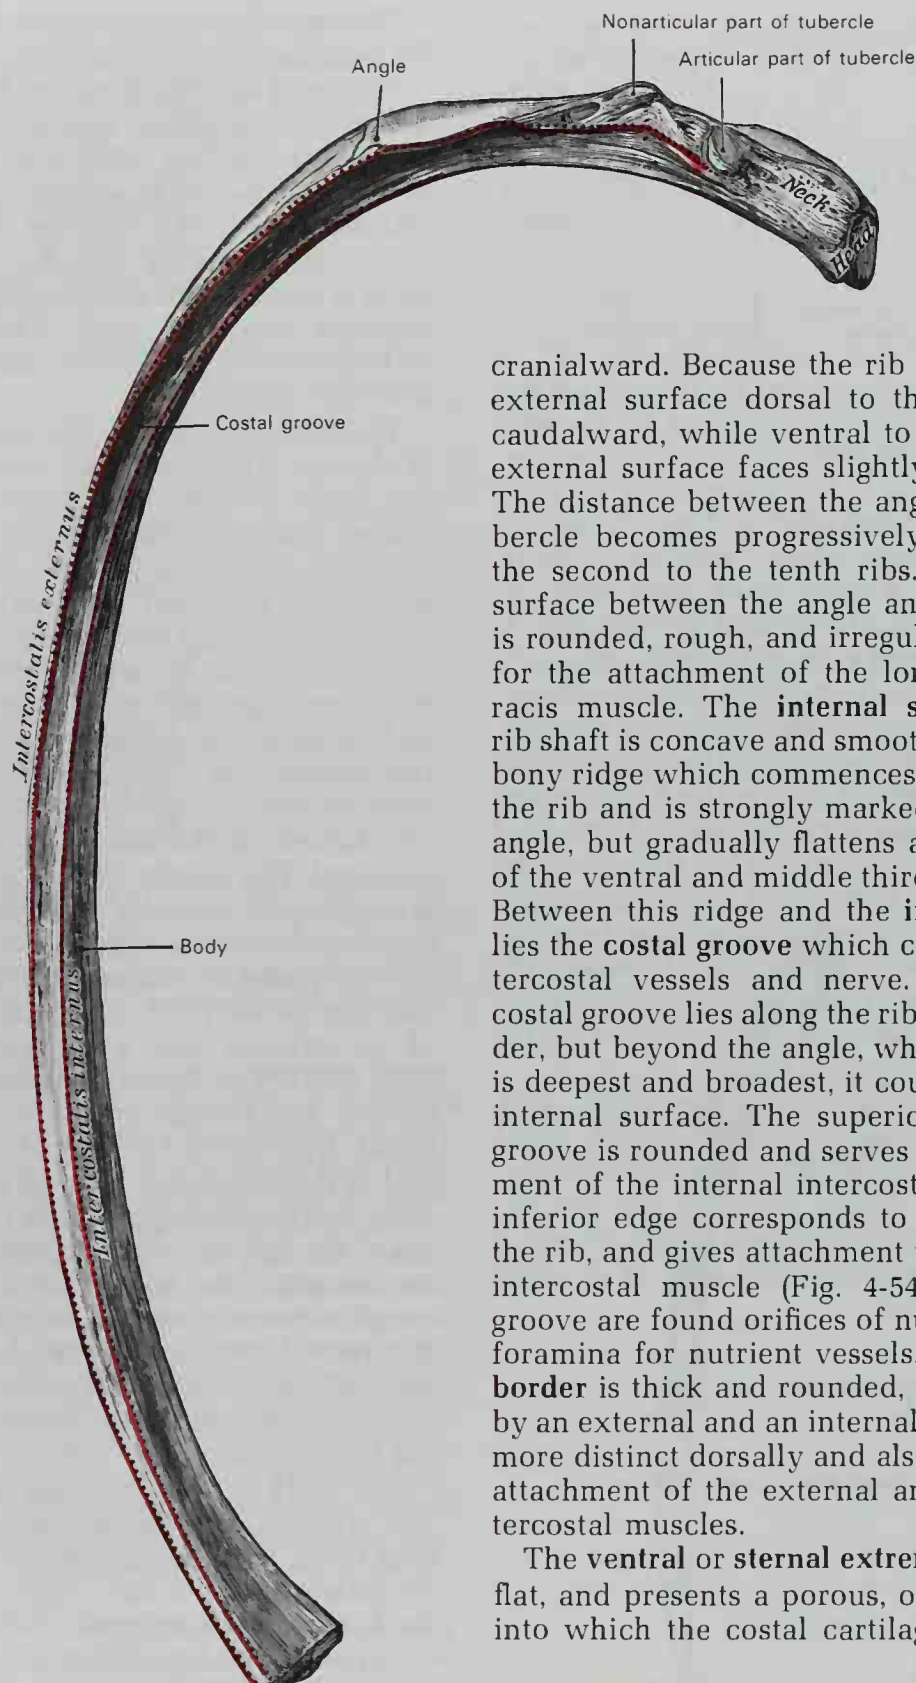

The **dorsal or vertebral extremity** presents for examination a head, neck, and tubercle.

The **head** is marked by two articular facets which are separated by a horizontal **inter-articular crest** (Fig. 4-55). The more inferior of the two facets is usually the larger and articulates onto the centrum of the segmentally corresponding vertebra. The cranial facet is smaller and articulates with the next superior vertebral body. The crest is attached to the intervertebral disc by the inter-articular ligament.

The **neck** (Fig. 4-55) is the flattened portion of the rib which extends lateralward from the head. It is about 2.5 cm long, and is placed ventral to the transverse process of the more caudal of the two vertebrae with which the rib head articulates. Its ventral surface is flat and smooth; its dorsal surface is roughened for the attachment of the costotransverse ligament (of the neck of the rib) and perforated by numerous foramina. Of its two borders the cranial is roughest and presents a sharp crest (*crista colli costae*) for the attachment of the anterior costotransverse ligament. The caudal border is rounded and is continuous laterally with the ridge of the costal groove. The **tubercle** is an eminence on the posterior surface of the rib at the junction of the neck and body, and consists of an articular and a nonarticular portion (Fig. 4-55). The articular portion, the more caudal and medial of the two, presents a small, oval facet for articulation with the end of the transverse process of the numerically corresponding vertebra (the more caudal of the two vertebrae to which the head is connected). The nonarticular portion is a rough elevation, and affords attachment to the lateral costotransverse ligament (ligament of the tubercle of the rib). The tubercle is much more prominent in the upper than in the lower ribs.

The **body or shaft** of a rib is thin and flat and presents an external and an internal surface along with two borders, a superior and an inferior. About six centimeters beyond the tubercle, the **external surface** is marked by a prominent line which gives attachment to a tendon of the iliocostalis muscle. At this site the shaft of the rib turns ventrally at a point, the **angle**. The rib is bent in two directions, and at the same time twisted on its long axis. If placed upon its inferior border, the portion dorsal to the angle is bent medialward and at the same time tilted

**FIG. 4-54.** The inferior aspect of a typical central rib from the left side. Note that the principal parts of the bone include the head, neck, tubercle (which possesses an articular eminence and a nonarticular eminence), and the curved body or shaft. The costal groove lodges the intercostal vessels and nerve.

cranialward. Because the rib is twisted, the external surface dorsal to the angle looks caudalward, while ventral to the angle, the external surface faces slightly cranialward. The distance between the angle and the tubercle becomes progressively greater from the second to the tenth ribs. The external surface between the angle and the tubercle is rounded, rough, and irregular, and serves for the attachment of the longissimus thoracis muscle. The **internal surface** of the rib shaft is concave and smooth, except for a bony ridge which commences at the head of the rib and is strongly marked as far as the angle, but gradually flattens at the junction of the ventral and middle thirds of the bone. Between this ridge and the **inferior border** lies the **costal groove** which contains the intercostal vessels and nerve. Dorsally, the costal groove lies along the rib's inferior border, but beyond the angle, where the groove is deepest and broadest, it courses along the internal surface. The superior edge of the groove is rounded and serves for the attachment of the internal intercostal muscle; the inferior edge corresponds to the margin of the rib, and gives attachment to the external intercostal muscle (Fig. 4-54). Within the groove are found orifices of numerous small foramina for nutrient vessels. The **superior border** is thick and rounded, and is marked by an external and an internal lip, which are more distinct dorsally and also serve for the attachment of the external and internal intercostal muscles.

The **ventral or sternal extremity** of a rib is flat, and presents a porous, oval depression into which the costal cartilage is received.

#### PECULIAR RIBS

The first, second, tenth, eleventh, and twelfth ribs present certain variations from the common characteristics described above, and require special consideration.

The **first rib** (Fig. 4-56) is the most curved

**FIG. 4-55.** A typical central rib from the left side viewed from behind. Observe that the vertebral extremity at the head end of the rib contains a large inferior facet for the numerically corresponding vertebra and a smaller facet for the adjacent vertebra above. Between them is the interarticular crest which attaches to the intervertebral disc.

and usually the shortest of all the ribs. It is broad and flat, its surfaces face cranially and caudally, and its borders internally and externally. The rounded head is small, and possesses only a single articular facet by which it articulates with the body of the first thoracic vertebra. The neck is narrow and also rounded, while the tubercle, thick and prominent, is placed on the outer border. There is no angle, but at the tubercle the rib is slightly bent, presenting a cranial convexity. The **superior surface** of the body is

marked by two shallow grooves, separated from each other by a slight ridge prolonged internally as the **scalene tubercle**, onto which attaches the scalenus anterior muscle. The ventral groove transmits the subclavian vein; the dorsal groove, the subclavian artery and the inferior trunk of the brachial plexus (Fig. 4-56). Beyond the dorsal groove is a rough area for the insertion of the scalenus medius. The **caudal surface** is smooth, and has no costal groove. The **outer border** is convex, thick, and rounded, and at

**FIG. 4-56.** The right first rib viewed from above. Observe the large tubercle below the rib head and the scalene tubercle accentuating the shaft.

**FIG. 4-57.** The right second rib viewed from above. Note the small tubercle, the slight angle nearby, and the tuberosity for serratus anterior.

its dorsal part gives origin to the first digitation of the serratus anterior. The inner border is concave, thin, sharp, and marked near its center by the scalene tubercle already described. The anterior (sternal) extremity is larger and thicker than that of any other rib and gives origin to the subclavius muscle.

The **second rib** (Fig. 4-57) is considerably longer than the first, but has a similar curvature. The nonarticular portion of the tubercle is small and the angle, situated close to the tubercle, is slight. The body shaft of the rib is not twisted, so that both ends touch any plane surface upon which it may be laid. The shaft is not flattened horizontally like that of the first rib, but proceeding ventrally from the tubercle, there is a cranial convexity, which is smaller than that seen in the first rib. Near the middle of its **outer surface** is the roughened **tuberosity of the second rib**, on which arises part of the first and the whole of the second digitation of the serratus anterior. Extending dorsally from the tuberosity is the insertion of the scalenus posterior. The internal surface is smooth and concave, and on its posterior part there is a short costal groove.

The **tenth rib** (Fig. 4-58) usually has only a single articular facet on its head for articulation with the body of the tenth thoracic vertebra.

The **eleventh and twelfth ribs** (Figs. 4-59; 4-60) each have a large single articular facet

on the rib head for articulation with the centrum of their respective vertebra. These two ribs have no necks or tubercles, and are narrow or pointed at their anterior ends. The eleventh has a slight angle and a shallow costal groove, but the twelfth has neither. It is much shorter than the eleventh, and at times even shorter than the first. Its head is inclined slightly upward.

### COSTAL CARTILAGES

The **costal cartilages** (*cartilagine costales*; Figs. 4-46; 4-49) are bars of hyaline cartilage which prolong the ribs ventrally, and which render the chest wall a more elastic nature in order to accommodate, among other things, the movements of respiration. The first seven pairs are connected with the sternum; the next three each articulate with the lower border of the cartilage of the preceding rib; the last two have pointed anterior extremities which end in the musculature of the abdominal wall. They increase in length from the first to the seventh, then gradually decrease to the twelfth. Their breadth diminishes from the first to the last, as do the intercostal spaces between them. The first two are the same breadth throughout their extent, while the third, fourth, and fifth are broader at their lateral attachments to the ribs than at their sternal ends. The sixth, seventh, and eighth are enlarged where their margins are in contact. The cartilages also

**Figs. 4-58 to 4-60.** Peculiar or atypical ribs. Each has but a single facet on its rib head. The eleventh and twelfth have no neck or tubercle, and the twelfth has no angle or costal groove.

vary in their orientation; the first three are horizontal, the others angular. Each costal cartilage presents two surfaces, two borders, and two extremities.

The **ventral surface** of the first cartilage gives attachment to the costoclavicular ligament and the subclavius muscle. The sternal ends of the first six or seven cartilages give origin to the pectoralis major (Fig. 4-49). The lower costal cartilages are covered by, and give partial attachment to, some of the flat muscles of the abdomen. The **dorsal surface** of the first cartilage gives attachment to the sternothyroid muscle, those of the third to the sixth inclusive to the transversus thoracis, and the last six or seven to the transversus abdominis and diaphragm.

The **superior borders** are concave while the **inferior borders** are convex. They afford attachment to the internal intercostal muscles along with the external intercostal membranes. Generally, the upper aspect of the fifth and sixth cartilages also give origin to some fibers of the pectoralis major. The inferior borders of the sixth, seventh, eighth, and ninth cartilages present heel-like projections at their points of greatest convexity. These projections bear smooth oblong facets which articulate with facets on slight projections from the superior borders of the seventh, eighth, ninth, and tenth cartilages, respectively.

**EXTREMITIES.** The lateral end of each cartilage is continuous with the osseous tissue of its corresponding rib. The medial end of the first is continuous with the sternum, while the rounded medial ends of the six succeeding ones are received into shallow concavities on the lateral margins of the sternum (Fig. 4-51). The medial ends of the eighth, ninth, and tenth costal cartilages are more pointed, and each is connected with the cartilage immediately above. Those of the eleventh and twelfth are pointed and free. In old age the costal cartilages are prone to lose some of their elasticity and undergo superficial ossification.

**STRUCTURE.** The ribs consist of highly vascular cancellous bone enclosed in a thin layer of compact bone.

**OSSIFICATION.** Cartilaginous models of the ribs are seen in the eight-week-old fetus. At about this time a primary ossification center develops near the angle of the rib shaft. Generally this is seen first in

the sixth and seventh ribs. Three additional epiphyseal centers, one for the head and one each for the articular and nonarticular parts of the tubercle, develop postnatally. The epiphyses for the head and tubercle make their appearance between the sixteenth and twentieth years, and are united to the body about the twenty-fifth year. The first rib has only three ossification centers, a primary center for the shaft and one secondary center for the rib head and only one for the tubercle. The eleventh and twelfth ribs each have only two centers, those for the tubercles being wanting.

**VARIATIONS AND CLINICAL INTEREST.** **Cervical ribs** derived from the costal process of the seventh cervical vertebra (Fig. 4-8) are not infrequent (about 1%) and are important clinically because they may give rise to neural and vascular symptoms. The cervical rib may be a mere epiphysis articulating only with the transverse process of the vertebra, but more commonly it consists of a defined head, neck, and tubercle, with or without a body. It extends laterally into the posterior triangle of the neck where it may terminate freely or join the first thoracic rib, the first costal cartilage, or even the sternum. It may vary much in shape, size, direction, and mobility. If a cervical rib reaches far enough ventrally, the roots or trunks of the brachial plexus and the subclavian artery and vein cross over it and are apt to be compressed. Pressure on the artery may obstruct the circulation while pressure on the nerves, especially the lower trunk of the brachial plexus (eighth cervical and first thoracic), may cause paralysis, pain, and paresthesia.

The thorax is frequently altered in shape by certain diseases. **Rickets** causes the ends of the ribs to become enlarged where they join the costal cartilages, giving rise to the so-called "**rachitic rosary**," which in mild cases is only found on the internal surface of the thorax. Lateral to these bead-like enlargements, the softened ribs are depressed, leaving a groove along each side of the sternum, which in turn is forced outward by the bending of the ribs, thereby increasing the dorsoventral diameter of the chest. The ribs so affected are the second to the eighth. Those below are prevented from being depressed by the underlying abdominal organs. Since liver and spleen enlargement frequently occurs in rickets, the abdomen becomes distended and the lower ribs may be pushed anteriorly, causing a transverse groove just above the costal arch. This deformity or forward projection of the sternum, often asymmetrical, is known as **pigeon breast**, and may be taken as evidence of active or old rickets except in cases of primary spinal curvature.

An opposite condition known as **funnel breast** occurs in some rachitic children or adults, and also in others who give no further evidence of having had rickets. The lower part of the sternum is deeply depressed backward, producing an oval hollow in the lower sternal and upper epigastric regions. This does

not appear to produce disturbances in vital functions.

The flattened **phthisical chest**, sometimes seen in pulmonary tuberculosis, is long and narrow, presenting a great obliquity of the ribs and projection of the scapulae. Contrastingly, the **barrel chest** of pulmonary emphysema is enlarged in all its diameters, and presents on section an almost circular outline.

In severe cases of **scoliosis**, or lateral curvature of the vertebral column, the thorax becomes much distorted. Due to rotation of the vertebral bodies, the ribs opposite the convexity of the dorsal curve become extremely convex behind. This distortion results in a bulging of the ribs posteriorly and a flattening anteriorly, so that the two ends of the same rib are almost parallel. Coincidentally, the ribs on the opposite side, i.e., on the concavity of the curve, are sunken and depressed behind, and bulging and convex in front.

## THE SKULL

The **skull**, or bony framework of the head, presents by far the most complex skeletal anatomy of the body. Lodging and protecting the vitally required brain with its equally important vasculature, the human head, as in other vertebrates, contains organs housing the special senses of sight, hearing, balance, taste, and smell, as well as structures in the mouth and nasal cavity related to the specialized life-maintaining mechanisms of feeding, respiration, and communication. The fact that food is ingested into the oral cavity, and that this entrance to the digestive tract is located conveniently close to visual, auditory, and olfactory receptors, and to the brain itself, is probably more than coincidental.

The bones of the head may be divided into two types: (1) those of the **cranium**, which enclose the brain and consist of eight bones, and (2) those of the **skeleton of the face**, numbering fourteen bones. For the most part the bones are either flat or irregular and, except for the mandible, are joined to each other by immovable articulations called **sutures**. Prior to describing the characteristics of each separate bone, important features of the anatomy of the skull as a whole will be outlined. The exterior of the skull may be viewed from above (**norma verticalis**); from the side (**norma lateralis**); toward the face (**norma frontalis**); from the back (**norma occipitalis**); and from below (**norma basalis**).

## Exterior of the Skull

### NORMA VERTICALIS

The skull cap or **calvaria**, viewed from above, varies greatly in different skulls. In some skulls its shape is more or less oval, in others more nearly circular. It is traversed by three sutures: (1) the **coronal suture**, nearly transverse in direction, between the frontal and parietal bones; (2) the **sagittal suture**, placed in the midline, between the two parietal bones, and (3) the upper part of the **lambdoidal suture**, separating the parietals and the occipital. The point of junction of the sagittal and coronal sutures is named the **bregma**, and the junction of the sagittal and lambdoid sutures is called the **lambda**. In the adult skull, these two sites indicate the positions of the anterior and posterior fontanelles, or the so-called soft spots in the skull of an infant. On each side of the sagittal suture are the **parietal eminences** where the smooth, rounded surface of the parietal bones is maximally convex. Lateral to the sagittal suture and anterior to the lambda may be found, on one or both sides, the **parietal foramen**, through which courses a small emissary vein. A cranio-metric term, **obelion**, is applied to that point on the sagittal suture at the level of the parietal foramina, while the **vertex**, near the middle of the sagittal suture, is the topmost point of the skull. Anteriorly, the frontal eminences form the two prominences of the forehead. Below these is a smooth prominence above the root of the nose, the **glabella**, on each side of which are the two **superciliary arches**. Immediately above the glabella, in a small percentage of skulls, a frontal suture persists and extends along the midline to the bregma.

### NORMA LATERALIS (Fig. 4-61)

Both cranial and facial bones of the skull can be inspected from the lateral aspect. Visible are the frontal, parietal, occipital, temporal, and zygomatic bones, as well as the great wing of the sphenoid, the orbital lamina of the ethmoid, and the lacrimal, nasal, and maxillary bones. The mandible also can be seen, but its description here is omitted. The following sutures can be observed from a lateral view: **temporozygomatic**, **frontozy-**

FIG. 4-61. Side view of the skull. (Norma lateralis.)

gomatic, squamosal, zygomaticomaxillary, and surrounding the great wing of the sphenoid—the **sphenofrontal**, **sphenoparietal**, and **sphenosquamosal** sutures. Additionally, several sutures on the medial aspect of the orbit between the lacrimal, ethmoid, maxillary, and frontal bones can be seen, as well as those sutures that extend laterally from above. Near the posterior base of the skull is the **occipitomastoid suture** joining the occipital and temporal bones. The sphenoparietal suture varies in length in different skulls, and is absent when the frontal bone articulates with the temporal squama. The point corresponding with the posterior end of the sphenoparietal suture is named the **pterion**. It is situated about 4 cm above the zygomatic arch and about 3 cm posterior to the frontozygomatic suture. The pterion overlies the anterior division of the middle meningeal artery.

The **squamosal suture** arches posteriorly from the pterion and lies between the tem-

poral squama and the inferior border of the parietal. This suture is continuous posteriorly with the short, nearly horizontal **parietomastoid suture**, which unites the mastoid process of the temporal with the parietal bone at its mastoid angle.

Extending across the cranium are the coronal and lambdoidal sutures, of which the latter is continuous with the occipitomastoid suture. The mastoid foramen, which transmits an emissary vein, lies in or near the occipitomastoid suture. The meeting point of the parietomastoid, occipitomastoid, and lambdoidal sutures is known as the **asterion**. Arching across the side of the cranium are the temporal lines (Fig. 4-61), which mark the superior limit of the temporal fossa.

The **temporal fossa** (*fossa temporalis*) is a region on the lateral aspect of the skull occupied by the temporalis muscle which arises from the cranium as far superiorly as the **temporal lines** (Fig. 4-61). Extending from the zygomatic process of the frontal bone

anteriorly, these two lines cross the frontal and parietal bones. Behind, they then curve anteriorly to become continuous with the supramastoid crest and the posterior root of the zygomatic arch. The craniometric term **stephanion** refers to the point where the **superior temporal line** cuts the coronal suture. The **inferior temporal line** lies somewhat below the superior. The temporal fossa is bounded *anteriorly* by the frontal and zygomatic bones. *Inferiorly*, it is separated from the infratemporal fossa by the **infratemporal crest** on the great wing of the sphenoid (Fig. 4-62), and by a ridge, continuous with this crest, which is carried posteriorly across the temporal squama to the anterior root of the zygomatic process. *Laterally* the temporal fossa is limited by the zygomatic arch. The fossa communicates with the orbital cavity through the **inferior orbital fissure** and, inferiorly, the temporal fossa is directly continuous with the **infratemporal fossa**. The floor of the fossa is deeply concave anteriorly and convex behind, and is formed by the zygomatic, frontal, parietal, sphenoid, and temporal bones. The temporal fossa contains the temporalis muscle and its ves-

sels and nerves, together with the zygomaticotemporal nerve. The muscle descends to its insertion on the coronoid process of the mandible medial to the zygomatic arch.

The **zygomatic arch** is formed by the zygomatic process of the temporal bone and the temporal process of the zygomatic bone, the two being united by an oblique suture. The arch can easily be felt, extending anteriorly from the external auditory meatus. At its junctions with the squamous part of the temporal bone, the zygomatic process broadens into two bony ridges or roots. An **anterior root** is directed medially to the mandibular fossa, where it expands to form the articular tubercle. The **posterior root** expands posteriorly above the external acoustic meatus and is continuous with the supramastoid crest. The superior border of the zygomatic arch gives attachment to the temporal fascia, while the inferior border and medial surface give origin to the masseter muscle.

Between the posterior root of the zygomatic arch and the mastoid process is the elliptical orifice of the **external acoustic meatus** (Fig. 4-62). The opening is principally bounded by the tympanic part of the tempo-

Fig. 4-62. Left infratemporal fossa as observed from the left lateral aspect with the zygoma cut.

ral bone, although its superior margin is formed by the squamous part of the temporal bone. The cartilaginous segment of the external auditory canal is fixed to this roughened outer bony margin. The small triangular area between the posterior root of the zygomatic arch and the posterosuperior part of the orifice is termed the **suprameatal triangle**, on the anterior border of which is sometimes seen a small spinous process, the **suprameatal spine**. Deep to this triangular area lies the mastoid antrum of the middle ear. Between the tympanic part of the temporal bone and the articular tubercle lies the **mandibular fossa**, which is divided into two parts by the **petrotympanic fissure**. The anterior and larger part of the fossa receives the condyle of the mandible, while the posterior part is nonarticular and sometimes lodges a portion of the parotid gland. The delicate and pointed **styloid process** extends downward and forward for a distance of 2.5 to 3.0 cm from the undersurface of the temporal bone inferior to the external acoustic meatus. It gives attachment to the styloglossus, stylohyoid, and stylopharyngeus muscles and to the stylohyoid and stylomandibular ligaments. Posterior to the external acoustic meatus is the **mastoid process**, to the outer surface of which are inserted the sternocleidomastoideus, splenius capitis, and longissimus capitis. The posterior belly of the digastric muscle arises from the mastoid notch, which grooves the medial aspect of the process.

The **infratemporal fossa** (*fossa infratemporalis*; Fig. 4-62) is an irregularly shaped cavity situated below and medial to the zygomatic arch. It is bounded in front by the infratemporal surface of the maxilla; behind by the articular tubercle of the temporal bone and the spine of the sphenoid bone; above by the great wing of the sphenoid and by the undersurface of the temporal squama; below by the alveolar border of the maxilla; medially by the lateral pterygoid plate of the sphenoid; and laterally by the zygomatic arch. It contains part of the temporalis and the medial and lateral pterygoid muscles, the maxillary vessels, the mandibular and maxillary nerves, and the pterygoid plexus of veins. The foramen ovale and foramen spinosum open into it from above, while the alveolar canals open on its anterior wall. At its superior and medial part are two fissures which meet at right angles, the horizontal

limb being named the **inferior orbital fissure**, and the vertical limb the **pterygomaxillary fissure**.

The **inferior orbital fissure** (*fissura orbitalis inferior*) opens into the posterolateral part of the orbit (Figs. 4-61, 4-62). It is bounded above by the inferior border of the orbital surface of the great wing of the sphenoid; below by the lateral border of the orbital surface of the maxilla and the orbital process of the palatine bone; laterally by a small part of the zygomatic bone; and medially it joins the pterygomaxillary fissure at right angles. Through the inferior orbital fissure, the orbit communicates with the temporal, infratemporal, and pterygopalatine fossae. It transmits the maxillary nerve, its zygomatic branch, ascending branches from the pterygopalatine ganglion, the infraorbital vessels, and the clinically important vein that connects the inferior ophthalmic vein with the pterygoid venous plexus.

The **pterygomaxillary fissure** is oriented vertically and descends at right angles from the medial end of the inferior orbital fissure (Fig. 4-61). It is a triangular interval, formed by the divergence of the maxilla from the pterygoid process of the sphenoid. It connects the infratemporal fossa with the **pterygopalatine fossa**, and transmits the terminal part of the maxillary artery and veins.

The **pterygopalatine fossa** (*fossa pterygopalatina*; Fig. 4-63) is a small cone-shaped or pyramidal region at the junction of the inferior orbital and pterygomaxillary fissures. It lies just beneath the apex of the orbit and is bounded above by the inferior surface of the body of the sphenoid bone and the orbital process of the palatine bone; in front by the infratemporal surface of the maxilla; behind by the base of the pterygoid process and the lower part of the anterior surface of the sphenoid bone; and medially by the perpendicular plate of the palatine bone. This fossa communicates with the orbit through the **inferior orbital fissure**, with the nasal cavity by the **sphenopalatine foramen**, and with the infratemporal fossa by way of the **pterygomaxillary fissure**. Additionally, the pterygopalatine fossa communicates with the cranial cavity by way of the **pterygoid canal**, which extends to the foramen lacerum, and with the roof of the oral cavity through the **pterygopalatine canal**. Of these five communicating foramina, the inferior orbital fissure opens anteriorly into the fossa while the

**Fig. 4-63.** The pterygopalatine fossa and the lateral wall of the right orbit.

foramen rotundum and pterygoid canal are posterior. On the medial wall is the sphenopalatine foramen and below is found the pterygopalatine canal. The fossa contains the maxillary nerve, the pterygopalatine ganglion, and the terminal part of the maxillary artery.

#### **NORMA FRONTALIS** (Fig. 4-64)

The facial aspect of the skull is outlined by the frontal bone superiorly, below which are the nasal bones, maxilla, and body of the mandible medially, and the zygomatic bones and rami of the mandible laterally. The **frontal eminences** stand out more or less prominently above the **superciliary arches**, which merge into one another at the **glabella**. Below the glabella is the **frontonasal suture**, the midpoint of which is termed the **nasion**. Lateral to the frontonasal suture and at the medial margin of the orbit, the frontal bone articulates with the frontal process of the maxilla and with the lacrimal. Below the superciliary arches, the superior part of the orbital margin is thin and prominent in its lateral two-thirds, but rounded and more massive in its medial third. At the junction of these two portions is the **supraorbital foramen** or **notch** for the supraorbital nerve and vessels. The **supraorbital margin** ends laterally in the **zygomatic process** of the frontal bone (Fig. 4-65), which articulates with the zygomatic bone. Below the fronto-

nasal suture is the bridge of the nose, formed by the two nasal bones supported posteriorly in the midline by the **perpendicular plate** of the ethmoid, and laterally by the **frontal processes** of the maxillae, which form the lower and medial part of the margin of each orbit. The **bony anterior nasal aperture** is bounded by the sharp margins of the nasal and maxillary bones. The **lateral** and **alar cartilages** of the nose are attached to the lateral nasal margins, while the inferior margins are thicker and end in the **anterior nasal spine** medially. The bony septum that separates the nasal cavity in the midline shows a large triangular deficiency in the bone anteriorly. This is filled by **septal cartilage** in the intact body. On the lateral wall of each nasal cavity the anterior part of the **inferior nasal concha** is visible.

Below and on each side of the pear-shaped aperture of the nose are the **maxillae**, which articulate in the midline and form much of the anterior bony substructure of the face. The anterior surface of the maxilla is perforated near the inferior margin of the orbit by the **infraorbital foramen** for the passage of the infraorbital nerve and vessels. Inferiorly, the **alveolar process** of each maxilla contains the osseous sockets for the upper teeth. The vertical ridges formed by the roots of the teeth are clearly visible, and that of the canine tooth, the **canine eminence**, is the most prominent.

The zygomatic bone forms the promi-

FIG. 4-64. The skull from the front. (Norma frontalis.)

nence of the cheek, the inferior and lateral portion of the orbital cavity, and the anterior part of the zygomatic arch. On the face it articulates medially with the maxilla, superiorly with the zygomatic process of the frontal bone, and laterally with the zygomatic process of the temporal bone. The zygomatic bone is perforated by the zygomaticofacial foramen for the passage of the zygomaticofacial nerve.

The maxillae rest on the **mandible**, or lower jaw, which extends from a characteristically human bony landmark, the chin or **mental protuberance** on the mandibular body, to the mandibular fossae laterally, where the mandibular **rami** articulate with the temporal bones. Lateral to the mental protuberance are the **mental tubercles**. The superior or alveolar border contains the

sockets for the lower teeth. Below the incisor teeth is the incisive fossa, and inferior to the second premolar tooth is the **mental foramen**, which transmits the mental nerve and vessels. An **oblique line** courses posteriorly from the mental tubercle and becomes continuous with the anterior border of the ramus. The posterior border of the ramus is directed downward and forward from the **condyle** to the **angle**. The latter frequently is more or less everted.

#### THE ORBITS (orbitae; Fig. 4-65)

The orbits are conical cavities which contain the eyeballs and their associated structures and are so placed that their medial walls are approximately parallel with each other and with the midline, but their lateral

**FIG. 4-65.** The anterior aspect of the right orbital cavity. Note the superior orbital fissure, inferior orbital fissure, and optic foramen within the orbital cavity, and the supraorbital, infraorbital, and zygomaticofacial foramina opening onto the surface.

walls are widely divergent. Thus, the longitudinal axes of the two orbits diverge widely anteriorly, but if prolonged posteriorly, they would cross dorsal to the body of the sphenoid bone near the center of the base of the skull. It is customary to describe the orbits in terms of a roof, a floor, a medial wall, a lateral wall, a base, and an apex.

The **roof** of the orbit (see Fig. 4-191), which separates the orbital contents from the overlying frontal lobes of the brain, is formed by the thin **orbital plate** of the frontal bone and the **lesser wing** of the sphenoid bone. The orbital surface of this plate presents medially the **trochlear fovea** for the attachment of the cartilaginous pulley of the obliquus superior oculi laterally. Anterolaterally is located the deep **lacrimal fossa** for the orbital part of the lacrimal gland. The posterior end of the orbital roof is marked by the **spheno-frontal suture**.

The **floor** of the orbit (Fig. 4-66) is formed chiefly by the orbital surface of the maxilla,

but also by the orbital process of the zygomatic bone, and to a small extent by the orbital process of the palatine. Near the orbital margin medially is the lacrimal sulcus for the **nasolacrimal canal**, and just lateral to this a small depression for the origin of the obliquus inferior oculi. Located laterally is the maxillozygomatic suture, and at its posterior part is the suture between the maxilla and the orbital process of the palatine (palatomaxillary suture). Near the middle of the floor is the **infraorbital groove**, which leads anteriorly into the **infraorbital canal** and transmits the infraorbital nerve and vessels to the anterior aspect of the face.

The **medial wall** (Fig. 4-67) is delicate and oriented nearly vertically. It is formed by the frontal process of the maxilla, the lacrimal bone, the lamina orbitalis of the ethmoid, and a small part of the body of the sphenoid. Anteriorly, the **lacrimal fossa** is a hollow region between the lacrimal bone and the frontal process of the maxilla. It lodges the

**FIG. 4-66.** Horizontal section through the right orbit demonstrating the bony floor of the orbital cavity from above. Observe the infraorbital groove and the longitudinally oriented suture between the maxilla and the zygomatic bone.

lacrimal sac and is limited behind by the **posterior lacrimal crest**, from which the lacrimal part of the orbicularis oculi arises. The medial wall contains three vertical sutures: the **lacrimomaxillary**, **lacrimoethmoidal**, and **sphenoethmoidal**. At the junction of the medial wall and the roof are the **frontomaxillary**, **frontolacrimal**, **frontoethmoidal**, and **sphenofrontal** sutures. The point of junction of the anterior border of the lacrimal with the frontal is named the **dacryon**. In the frontoethmoidal suture are the **anterior** and **posterior ethmoidal foramina**, the former transmitting the anterior ethmoidal vessels and nerve, and the latter the posterior ethmoidal vessels and nerve. The nerves are branches of the nasociliary while the vessels are branches of the ophthalmic.

The **lateral wall** of the orbit (Fig. 4-63) is directed forward and medially and is formed by the orbital process of the zygomatic bone and the orbital surface of the great wing of the sphenoid. These two bones

articulate at the **sphenozygomatic suture**, which terminates at the anterior end of the **inferior orbital fissure**. Between the roof and the lateral wall, near the apex of the orbit, is the **superior orbital fissure**. Communicating with the cranial cavity, this fissure transmits the oculomotor, trochlear, ophthalmic division of the trigeminal, and abducent nerves to the orbit. Also entering the orbit through the superior orbital fissure are sympathetic nerve filaments from the cavernous plexus as well as the orbital branches of the middle meningeal artery. Leaving through the fissure for the cranial cavity are the superior ophthalmic vein and the recurrent branch from the lacrimal artery to the dura mater. The lateral wall and the orbital floor are separated posteriorly by the inferior orbital fissure.

The **base** of the orbit is its anterior end; it is formed by the orbital margin, and has already been described. The **apex** is situated at the back of the orbit and corresponds to

**FIG. 4-67.** Medial wall of left orbit. In this dissection the lateral wall of the left orbit has been removed in order to expose the medial wall, and the left maxillary sinus has been opened from the lateral aspect. Note that the medial wall of the orbit is formed by the maxilla, lacrimal, ethmoid, and, most posteriorly, the sphenoid bone. The ethmoid bone is shown in red, the palatine bone in blue.

the **optic foramen**, a short, cylindrical canal, which transmits the optic nerve and ophthalmic artery.

Ten openings communicate with each orbit: the optic foramen, superior and inferior orbital fissures, supraorbital foramen, infraorbital canal, anterior and posterior ethmoidal foramina, zygomaticofacial and zygomaticotemporal foramina, and the canal for the nasolacrimal duct.

#### **NORMA OCCIPITALIS**

When viewed from behind the cranium presents a circular, dome-like shape, except at its base, which is flattened. In the midline is observed the posterior continuation of the **sagittal suture**, which extends between the parietal bones to the deeply serrated **lambdoidal suture**. The latter lies between the parietal bones and the occipital and contin-

ues laterally into the **parietomastoid** and **occipitomastoid sutures**. Frequently, one or more sutural bones, such as an **interparietal (inca) bone**, may be interposed between the parietal and occipital bones. Near the middle of the occipital squama is the **external occipital protuberance**, and extending laterally from it on each side is the **superior nuchal line**. Also seen is the more faintly marked **highest nuchal line**, which extends laterally about 1 cm above the superior. If the skull is slightly elevated, the **inferior nuchal line** comes into view coursing laterally below the superior line. The **inion** is a craniometric term applying to the midline point on the external occipital protuberance. Descending from the inion to the **foramen magnum** is a bony ridge, the **external occipital crest**, which affords attachment to the ligamentum nuchae. Laterally and somewhat anteriorly on each side can be seen the mastoid process of the temporal bone, and near

the occipitomastoid suture is the mastoid foramen through which passes the mastoid emissary vein.

#### **NORMA BASALIS** (Figs. 4-68; 4-69)

With the mandible removed, the inferior surface of the base of the skull is formed by the palatine processes of the **maxillae**, the horizontal plates of the **palatine** bones, the **vomer**, the pterygoid processes, the inferior surfaces of the great wings, the spinous processes and part of the body of the **sphenoid**, the inferior surfaces of the squamae and petrous portions of the **temporals**, and the inferior surface of the **occipital** bone.

The *anterior part of the norma basalis* projects downward beyond the level of the rest of the basal surface and is formed principally by the **hard palate**. The bony palate is bounded anteriorly and laterally by the alveolar arch containing the sixteen teeth of the maxillae. Just behind the incisor teeth is found the **incisive fossa**. Within the fossa are two **lateral incisive foramina** (foramina of Stenson) which continue as the incisive canals and transmit the terminal branches of the greater palatine vessels and the nasopalatine nerves from the nasal cavity. Occasionally two other **median incisive foramina** (foramina of Scarpa) are found. When present they transmit the nasopalatine nerves. The vault of the hard palate is marked by depressions for the palatine glands. It is traversed by a cruciate suture formed by the junction of the two palatine processes of the maxillae and the two horizontal plates of the palatine bones of which it is composed. At either posterior angle of the hard palate is the **greater palatine foramen**, for the transmission of the greater palatine vessels and nerve, which descend in the greater palatine canal from the pterygopalatine fossa. Posterior to the foramen is the pyramidal process of the palatine bone, perforated by one or more **lesser palatine foramina** through which course the lesser palatine vessels and nerve to the soft palate. At this site also is observed a transverse ridge for the attachment of the tendinous expansion of the tensor veli palatini muscle. Projecting backward from the center of the posterior border of the hard palate is the **posterior nasal spine**, on which attaches the musculus uvulae.

The *middle part of the norma basalis*

commences just behind the hard palate and extends to the level of the anterior border of the foramen magnum. Just behind the hard palate are the **choanae** or posterior openings into the nasal cavities. They are separated by the vomer, and each is bounded above by the body of the sphenoid, below by the horizontal part of the palatine bone, and laterally by the medial pterygoid plate of the sphenoid. At the superior border of the vomer, the expanded alae of this bone receive between them the rostrum of the sphenoid. The **medial pterygoid plate** is long and narrow; on the lateral side of its base is the **scaphoid fossa**, for the origin of the tensor veli palatini muscle, and at its lower extremity the **pterygoid hamulus**, around which the tendon of this muscle turns. The **lateral pterygoid plate** is broad; its lateral surface forms the medial boundary of the infratemporal fossa, and affords attachment to the pterygoideus lateralis muscle.

Posterior to the vomer is the basilar portion of the occipital bone, presenting near its center the **pharyngeal tubercle** for the attachment of the fibrous raphe of the pharynx, with depressions on each side for the insertions of the rectus capitis anterior and longus capitis. At the base of the lateral pterygoid plate is the **foramen ovale**, through which passes the mandibular nerve and the accessory meningeal artery. Lateral to this is the prominent **sphenoidal spine**, which gives attachment to the sphenomandibular ligament and the tensor veli palatini. Posterior and somewhat lateral to the foramen ovale is the **foramen spinosum**, which transmits the middle meningeal vessels and a small meningeal branch of the mandibular nerve. Lateral to the sphenoidal spine is the **mandibular fossa**, which is divided into two parts by the **petrotympanic fissure**. The *anterior portion*—concave, smooth, and bounded in front by the articular tubercle—articulates with the condyle of the mandible; the *posterior portion* is rough and bounded behind by the tympanic part of the temporal bone.

Observable in a dried skull at the base of the medial pterygoid plate is an aperture, irregular in shape and variable in size, named the **foramen lacerum**. It is not a complete foramen in the intact body, because its inferior part is covered over by a fibrocartilaginous plate, across the superior (inner or cerebral) surface of which passes the internal

carotid artery. The foramen lacerum is bounded in front by the great wing of the sphenoid, behind by the apex of the petrous portion of the temporal bone, and medially by the body of the sphenoid and the basilar portion of the occipital bone. The inferior surface of the petrous temporal bone is pierced by the round opening of the **carotid canal**. The internal carotid artery, coursing within the canal, immediately takes a right-angle turn to reach the side of the foramen lacerum. At the upper end of the foramen lacerum the internal carotid artery enters the cranial cavity, taking an S-shaped course to achieve the undersurface of the brain. Lateral to the foramen lacerum is a groove, the **sulcus tubae auditivae**, between the petrous part of the temporal and the great wing of the sphenoid. This sulcus lodges the cartilaginous part of the **auditory tube** which is continuous with the bony part within the temporal bone. At the bottom of this sulcus is a narrow cleft, the **petrosphenoidal fissure**. Near the apex of the petrous portion of the temporal bone, the quadrilateral rough surface affords attachment to the levator veli palatini, lateral to which is the orifice or entrance of the carotid canal.

The posterior part of the *norma basalis* is formed principally by the occipital bone; however, laterally are the roughened, bony **mastoid processes** of the temporal bones. On the medial side of each mastoid process is the **mastoid notch** for the posterior belly of the digastricus, and medial to the notch is the occipital groove for the occipital artery. Medial and slightly anterior to the mastoid processes and emerging from between the laminae of the **vaginal process** of the tympanic part of the temporal bone is the **styloid process**, at the base of which is the **stylo-mastoid foramen**. Through this foramen the facial nerve exits in its course toward the side of the face, and the stylomastoid artery enters to supply the tympanic cavity of the middle ear. Medial to the styloid process and posterior to the carotid canal is the **jugular foramen**, a large aperture, formed between the jugular fossa of the petrous portion of the temporal bone anteriorly, and the occipital bone posteriorly. It is generally larger on the right than on the left side, and may be subdivided into three compartments. The anterior compartment transmits the inferior petrosal sinus; the intermediate, the glossopharyngeal, vagus, and accessory nerves; the

FIG. 4-68. The external surface of the left half of the base of the skull. (*Norma basalis*.)

posterior, the sigmoid sinus which leads to the internal jugular vein, and some meningeal branches from the occipital and ascending pharyngeal arteries. Extending anteriorly from the jugular foramen to the foramen lacerum is the **petro-occipital fissure**, occupied in the intact body by a plate of cartilage.

Posterior to the basilar portion of the occipital bone is the **foramen magnum**, bounded laterally by the **occipital condyles**, on the medial surfaces of which attach the alar ligaments. These condyles are oval in

FIG. 4-69. Key to Figure 4-68.

shape and project inferiorly to articulate with the superior articular surfaces overlying the lateral masses of the atlas. Lateral to each condyle is the **jugular process**, to which attaches the rectus capitis lateralis muscle and the lateral atlanto-occipital ligament, which strengthens the atlanto-occipital articular capsules laterally. The foramen magnum transmits the medulla oblongata and its membranes, the accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the ligaments connecting the occipital bone with the axis. The mid-

points on the anterior and posterior margins of the foramen are respectively termed the **basion** and the **opisthion**.

The **hypoglossal canal** courses forward and laterally from a foramen on the inner aspect of the occipital bone within the cranium just above the foramen magnum to an opening that perforates the occipital bone externally at the lateral part of the base of the condyle. It transmits the hypoglossal nerve and a branch of the posterior meningeal artery. Posterior to each condyle is the **condylod fossa**, perforated on one or both

sides by the **condyloid canal**, for the transmission of a vein from the sigmoid sinus to the vertebral veins in the upper cervical region. Posterior to the foramen magnum is the **external occipital crest**, ending superiorly at the **external occipital protuberance**. On either side are the **superior and inferior nuchal lines** which, along with the surfaces of bone between them, are rough for the attachment of a number of muscles (see Figs. 4-69; 4-85).

### *Interior of the Skull*

The **cranial cavity** is formed by the frontal, ethmoid, sphenoid, temporal, parietal, and occipital bones. The internal surface of the floor of the cranial cavity, i.e., the base of the skull, is quite irregular in shape, but the inner surfaces of the bones forming the walls and roof of the cranial vault are smoother and encase the rounded hemispheres of the cerebrum and cerebellum. The capacity of the normal cranial cavity varies between 1300 and 1500 cc, and the weight of the brain in grams is approximately the same as the figure for cranial capacity expressed in cubic centimeters. The cranial cavity is lined by two fibrous layers or membranes: the periosteal layer, or **endocranium**, which is closely adherent to the bone, and the **dura mater**, which is looser and completely covers the brain in a sac-like fashion. The interior of the skull will be described in two sections: the inner surface of the skullcap or **calvaria** and the internal surface of the base of the skull.

### INNER SURFACE OF THE SKULLCAP

Formed principally by the frontal and parietal bones, the skullcap, or **calvaria**, also includes the upper parts of the squamae of the temporal and occipital bones laterally and posteriorly. Its inner surface is marked by depressions for the convolutions of the cerebrum, and by numerous furrows for the branches of the meningeal vessels. Along the midline is a longitudinal groove, narrow where it commences at the **frontal crest**, but broader posteriorly. It lodges the superior sagittal sinus, and its margins afford attachment to the falx cerebri. On each side of this groove are several **granular foveolae** or pits for the arachnoid granulations, and posteriorly, the openings of the **parietal foramina**

when these are present. The coronal and lambdoidal sutures can be seen crossing the inner surface of the calvaria transversely while the sagittal suture lies in the median plane between the parietal bones.

### INTERNAL OR SUPERIOR SURFACE OF THE BASE OF THE SKULL (Fig. 4-70)

The superior surface of the base of the skull forms the **floor of the cranial cavity** and is divided into three fossae, called the anterior, middle, and posterior cranial fossae.

**ANTERIOR CRANIAL FOSSA** (*fossa cranii anterior*). The floor of the anterior cranial fossa, on which rest the frontal lobes of the brain, is formed by the **orbital plates** of the frontal, and **cribriform plate** of the ethmoid, and the **small wings** and **anterior part of the body** of the sphenoid. It is limited behind by the posterior borders of the small wings of the sphenoid and by the anterior margin of the chiasmatic groove. It is traversed by the **frontoethmoidal**, **sphenoethmoidal**, and **sphenofrontal sutures**. Its lateral portions or **orbital plates** are convex and form the bony roof of the orbital cavities. The middle portion, formed primarily by the ethmoid bone, overlies the nasal cavities. In the midline most anteriorly is the **frontal crest** (of the frontal bone) on which attaches the **falx cerebri**. Just behind this crest is the **foramen cecum**, which usually transmits a small vein from the nasal cavity to the superior sagittal sinus. The upward continuation of the perpendicular plate of the ethmoid bone forms a midline bony crest, the **crista galli**, to which also attaches the falx cerebri. On both sides of the crista galli, the **olfactory grooves** of the **cribriform plate** support the olfactory bulbs. These grooves are perforated by foramina for the transmission of the olfactory nerves and, more rostrally, by a slit for the **nasociliary nerve** (Fig. 4-70). In the lateral wall of the olfactory groove are the internal openings of the **anterior and posterior ethmoidal foramina**. The anterior transmits the anterior ethmoidal vessels and the nasociliary nerve; the posterior ethmoidal foramen opens more caudally under cover of the projecting lamina of the sphenoid, and transmits the posterior ethmoidal vessels and nerve. Behind the ethmoid bone are the **ethmoidal spine** of the sphenoid and the anterior margin of the **chiasmatic groove**. This groove courses laterally on each side to the

FIG. 4-70. Interior of base of the skull, showing the cranial fossae.

upper margin of the **optic foramen**. Through each optic foramen courses an optic nerve and ophthalmic artery.

**MIDDLE CRANIAL FOSSA** (*fossa cranii media*). The lateral parts of the middle cranial fossa are of considerable depth, and they support the temporal lobes of the brain.

More medially rests the hypothalamus and midbrain. On each side the middle fossa is bounded anteriorly by the posterior margins of the small wings of the sphenoid, the anterior clinoid processes, and the ridge forming the anterior margin of the chiasmatic groove; posteriorly, by the superior angles of the pet-

rous portion of the temporals and the *dorsum sellae*; *laterally* by the temporal squamae, sphenoidal angles of the parietals, and great wings of the sphenoid. The middle fossa on each side is traversed by the **squamosal, sphenoparietal, sphenosquamosal and sphenopetrosal sutures**.

In the anterior part of the median region are the **chiasmatic groove** and **tuberculum sellae**. On each side the chiasmatic groove ends at the optic foramen, posterior to which extends the **anterior clinoid process** that gives attachment to the tentorium cerebelli. Behind the tuberculum sellae, the **hypophyseal fossa** forms a deep depression in the **sella turcica** and lodges the hypophysis. A tubercle, the **medial clinoid process**, may be present on each side of the anterior wall of the **sella turcica**. The **sella turcica** is bounded posteriorly by a quadrilateral plate of bone, the **dorsum sellae**, the free angles of which are surmounted by the **posterior clinoid processes**. These afford attachment to the tentorium cerebelli, and below each is a notch for the abducent nerve. On each side of the **sella turcica** is the **carotid groove**, which is broad, shallow, and curved. The groove lodges the internal carotid artery and extends from the foramen lacerum to the medial side of the anterior clinoid process, where it is sometimes converted into a **caroticoclinoid foramen** by the union of the anterior with the medial clinoid process. The carotid groove also contains the cavernous sinus and may be bounded posterolaterally by the **lingula** of the sphenoid.

The bony lateral surface of the middle cranial fossa is traversed by furrows for the anterior and posterior branches of the **middle meningeal vessels**. Commencing near the **foramen spinosum**, the anterior furrow runs to the sphenoidal angle of the parietal, where it is sometimes converted into a bony canal; the posterior runs lateralward across the temporal squama, passing onto the parietal bone near the middle of its inferior border. The following apertures are also to be seen. Rostrally, the **superior orbital fissure** is bounded above by the small wing, below by the great wing, and medially by the body of the sphenoid; it is usually completed laterally by the orbital plate of the frontal bone. The fissure transmits: (1) to the *orbital cavity*—the oculomotor, the trochlear, the ophthalmic division of the trigeminal, and the abducent nerves, sympathetic nerve fibers

from the cavernous plexus, and the orbital branch of the middle meningeal artery; and (2) to the *cranial cavity* from the orbit—the ophthalmic veins and a recurrent branch of the lacrimal artery to the dura mater. Posterior to the medial end of the superior orbital fissure is the **foramen rotundum** through which passes the maxillary nerve. Posterolaterally is the larger **foramen ovale** through which courses the mandibular nerve, the accessory meningeal artery, and the lesser petrosal nerve. The **foramen of Vesalius**, often absent, opens at the lateral aspect of the scaphoid fossa inferiorly, and transmits a small vein. Lateral and posterior to the foramen ovale is the **foramen spinosum**, which transmits the middle meningeal vessels and a recurrent branch of the mandibular nerve which supplies the dura mater. Medial to the foramen ovale the **foramen lacerum** may be seen in a dried skull, but in the fresh state the inferior part of this aperture is occupied by a layer of fibrocartilage. The internal carotid artery, surrounded by a plexus of sympathetic nerves, passes across the superior part of the foramen but does not traverse its whole extent. The small nerve of the pterygoid canal and a small meningeal branch from the ascending pharyngeal artery alone pierce the layer of fibrocartilage and are thus the only structures to pass through the foramen lacerum. On the anterior surface of the petrous portion of the temporal bone is seen the **arcuate eminence** formed by the projection of the anterior semicircular canal. Also on this anterior surface of the petrous temporal bone is found a groove called the **hiatus for the greater petrosal nerve**. This nerve, coming from the geniculate ganglion of the facial nerve, courses along the groove and then traverses the foramen lacerum to join the deep petrosal nerve. A bit more lateral is another somewhat smaller **hiatus for the lesser petrosal nerve**, which is bound for the otic ganglion and leaves the cranial cavity through the foramen ovale or its own foramen. Behind the foramen lacerum can be seen the **depression for the trigeminal ganglion**.

**POSTERIOR CRANIAL FOSSA** (*fossa cranii posterior*). The posterior cranial fossa is the largest and deepest of the three. Within it lies the pons and medulla oblongata medially, over which expands the lobes of the cerebellum. The bony floor of this fossa is formed by the **dorsum sellae** and **clivus** of

the sphenoid, the occipital bone, the petrous and mastoid portions of the temporals, and the mastoid angles of the parietal bones. It is crossed by the occipitomastoid, parietomastoid, and sphenoccipital sutures. The posterior fossa is separated from the middle fossa in and near the midline by the dorsum sellae of the sphenoid and on each side by the grooved superior margin of the petrous portion of the temporal bone. This margin gives attachment to the tentorium cerebelli, and lodges in its groove the superior petrosal sinus. In the center of the posterior fossa is the **foramen magnum**, and on each of its lateral sides is the **hypoglossal canal**, through which courses the hypoglossal nerve and a meningeal branch from the ascending pharyngeal artery. Anterior to the foramen magnum, the basilar portion of the occipital and the posterior part of the body of the sphenoid form a grooved surface which supports the medulla oblongata and pons. In the young skull these bones are joined by a synchondrosis. This grooved basilar region is separated from the petrous temporal by the **petro-occipital fissure**, which is occupied in life by a thin plate of cartilage. The fissure is continuous with the **jugular foramen**, and its margins are grooved for the **inferior petrosal sinus**.

The **jugular foramen** is situated between the lateral part of the occipital and the petrous part of the temporal. The anterior portion of this foramen transmits the inferior petrosal sinus; the posterior portion, the sigmoid sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; and the intermediate portion, the glossopharyngeal, vagus, and accessory nerves. Superior to the jugular foramen is the **internal acoustic meatus**, for the facial and vestibulocochlear nerves and internal auditory artery. A narrow fissure is located behind and lateral to the meatus, which contains the external opening of the **aqueduct of the vestibule** (*aqueductus vestibuli*). In the aqueduct is located the endolymphatic duct. Behind the foramen magnum are the **inferior occipital fossae**, which support the hemispheres of the cerebellum. These are separated from one another by the **internal occipital crest**, which serves for the attachment of the falx cerebelli and lodges the occipital sinus. The posterior cranial fossae are bounded posterolaterally by S-shaped grooves for the sigmoid sinuses

which lead to the jugular foramen. Posteriorly these grooves are continuous with those of the **transverse sinuses**. These grooves accentuate the inner surface of the occipital bone, the mastoid angle of the parietal, the mastoid portion of the temporal, and the jugular process of the occipital, and end at the jugular foramen on each side. Where this sinus grooves the mastoid portion of the temporal, the orifice of the **mastoid foramen** may be seen, and just prior to its termination, the **condyloid canal** opens into it. Both of these orifices transmit emissary veins, but neither opening is constant.

**NASAL CAVITY** (*cavum nasi*; Figs. 4-64; 4-71 to 4-73). The **nasal cavities** are two irregularly shaped spaces which extend from the base of the cranium to the roof of the mouth. They are separated from each other in the midline by a thin vertical **septum**. They open on the face through a single pear-shaped **anterior nasal aperture**, since the anterior cartilaginous part of the septum is lacking in a dried skull. Posteriorly, two openings, the **choanae**, communicate with the nasal part of the pharynx. The nasal cavities are much narrower superiorly than inferiorly, and they communicate with the **frontal, maxillary, ethmoidal, and sphenoidal sinuses**. Each cavity is bounded by a roof, a floor, a medial wall, and a lateral wall.

The **roof** (Figs. 4-71; 4-72) is horizontal centrally, but slopes downward in front and behind. Its middle is 2 to 3 mm wide and is formed by the **cribriform plate** of the ethmoid bone, through which pass nearly 20 foramina for the filaments of the olfactory nerves. Anteriorly, the roof is formed by the nasal bone and the spine of the frontal, and posteriorly, by the body of the sphenoid, the ala of the vomer, and the sphenoidal process of the palatine bone. On the superior and posterior part of the roof is the **opening of the sphenoidal sinus**.

The bony **floor** (Fig. 4-22) is smooth and is formed by the **palatine process** of the maxilla and the **horizontal part** of the palatine bone. These represent the bones of the hard palate, which separate the nasal cavity from the oral cavity. Near the anterior end is the opening of the **incisive canal**, through which pass the nasopalatine nerves and branches of the greater palatine arteries.

The **medial wall** (*septum nasi*; Fig. 4-71) is the osseous **nasal septum** which separates

**FIG. 4-71.** Sagittal section of skull showing the osseous nasal septum formed principally by the perpendicular plate of the ethmoid bone and the vomer anteriorly. Behind and above the septum are seen the bones forming the inner surface of the cranial cavity.

**FIG. 4-72.** Roof, floor, and lateral wall of left nasal cavity.

**Fig. 4-73.** Lateral wall of the nasal cavity after the removal of the middle concha to expose the structures and orifices of the middle meatus. Arrows indicate openings from the frontal and sphenoid sinuses.

the two nasal cavities. It extends from the roof to the floor and is frequently deflected to one side or the other, more often to the left than to the right. Although cartilaginous in front, the septum is formed primarily by the **perpendicular plate of the ethmoid bone** and the **vomer**. Posteriorly, these bones articulate with the sphenoid, while anteriorly the crest of the nasal bones and the spine of the frontal also contribute to the septum.

The **lateral wall** (Figs. 4-72; 4-73) appears irregular, but in fact is a rather flat surface upon which are projected three curved laminae or **conchae**. This wall is formed, anteriorly, by the frontal process of the maxilla and by the lacrimal bone; in the middle, by the ethmoid, maxilla, and inferior nasal concha; posteriorly, by the vertical plate of the palatine bone, and the medial pterygoid plate of the sphenoid. On this wall are three curved anteroposterior passages, termed the superior, middle, and inferior meatuses of the nose (Fig. 4-72). The **superior meatus** is the shortest of the three and occupies the middle third of the lateral wall between the superior and middle nasal conchae. The **posterior ethmoidal cells** open into the superior

meatus, while the **sphenopalatine foramen**, an opening in the perpendicular plate of the palatine bone which serves as a means of communication between the pterygopalatine fossa and the nasal cavity, lies just behind the meatus. The orifice of the sphenoidal sinus drains into the **sphenoethmoidal recess**, which lies in the most superior and posterior part of the nasal cavity, formed by the angle of junction of the sphenoid and ethmoid bones. The **middle meatus** is situated between the middle and inferior conchae (Fig. 4-72), and it courses anteroposteriorly above the superior border of the inferior concha along its entire extent. The lateral wall of this meatus can be satisfactorily studied only after the removal of the middle concha (Fig. 4-73). A curved fissure, the **hiatus semilunaris**, lies along this meatus between the **uncinate process** of the ethmoid bone and the **bulla ethmoidalis**. The **middle ethmoidal cells** are contained within the bulla and open on or near it. The middle meatus communicates through the hiatus semilunaris with a curved passage termed the **infundibulum**, into which the **anterior ethmoidal cells** open. The **frontonasal duct**

leading from the frontal sinus opens into the anterior end of the infundibulum or directly into the anterior part of the middle meatus. Below the bulla ethmoidalis and hidden by the uncinate process of the ethmoid is the **opening of the maxillary sinus**, and an **accessory opening** frequently is present above the posterior part of the inferior nasal concha. The **inferior meatus** is the space between the inferior concha and the floor of the nasal cavity. It extends almost the entire length of the lateral wall of the nasal cavity, and presents anteriorly the **inferior orifice of the nasolacrimal canal**. Observe the locations of the frontal maxillary and sphenoid sinuses in Figure 4-74.

The **anterior nasal aperture** (Fig. 4-64) is a pear-shaped opening, the long axis of which is vertical. It is bounded superiorly by the inferior borders of the nasal bones; laterally by the thin, sharp margins which separate the anterior from the nasal surfaces of the maxillae; and inferiorly by the same borders,

where they curve medialward to join at the anterior nasal spine. Attached to the borders of the bony anterior nasal aperture are the external cartilages of the nose. These provide the principal surface features and shape of the external nose and open by way of two elliptical orifices, the **nares**.

The two **posterior nasal apertures**, or choanae, are bounded superiorly by the body of the sphenoid and ala of the vomer; inferiorly, by the posterior border of the horizontal part of the palatine bone, which actually forms the posterior part of the hard palate; and laterally, by the medial pterygoid plate. The choanae are separated from each other in the midline by the posterior border of the vomer.

### *Differences in the Skull Due to Age*

**At birth** the skull is large in proportion to the other parts of the skeleton, but the facial portion of the cranium in the newborn is small, and equals only

**FIG. 4-74.** Lateral view roentgenogram of the adult skull. Crosses are placed in the frontal, maxillary, and sphenoid sinuses. The hypophyseal fossa can be identified directly behind the sphenoid sinus. The dense white region below and behind the fossa is due to the petrous part of the temporal bone. (Courtesy of Doctors Moreland and Arndt.)

about one-eighth of the bulk of the skull compared to one-half in the adult. The smallness of the **face at birth** is due to the rudimentary condition of the maxillae and mandible, the noneruption of the teeth, and the small size of the maxillary air sinuses and nasal cavities. At birth the nasal cavities lie almost entirely between the orbits, and the lower border of the anterior nasal aperture is only a little below the level of the orbital floor. In contrast, the **cranial cavity** is large to accommodate the large neonatal brain. The frontal and parietal eminences are prominent, and the skull is maximally wide at the level of the parietal tubers (Fig. 4-75). On the other hand, the glabella, superciliary arches, and mastoid processes are not even developed at birth. Ossification of the skull bones is not completed, and many, e.g., the occipital, temporals, sphenoid, frontal, and mandible, consist of more than one piece. Unossified membranous intervals, termed **fontanelles**, are seen at the angles of the parietal bones. There are six fontanelles in number: two, an anterior and a posterior, are situated in the midline; two others are found on each side, an anterolateral (sphenoidal) and a posterolateral (mastoid).

The **anterior or bregmatic fontanelle** (*fonticulus anterior*; Fig. 4-75) is the largest, and is located at the junction of the sagittal, coronal, and frontal sutures. It is diamond-shaped and measures about 4 cm in its anteroposterior and 2.5 cm in its transverse diameter. The **posterior fontanelle** is triangular in form and is situated at the junction of the sagit-

tal and lambdoidal sutures. The **sphenoidal and mastoid fontanelles** (Fig. 4-76) are small, irregular in shape, and correspond respectively to the sphenoidal and mastoid angles of the parietal bones. The posterior and lateral fontanelles become closed within a month or two after birth, but the anterior does not completely close until about the middle of the second year.

**Postnatal growth** of the face and enlargement of the jaws are temporally correlated with the eruption of the deciduous teeth. These changes are still more marked after the second dentition. The skull grows rapidly from birth to the seventh year, by which time the foramen magnum and petrous parts of the temporal bones have reached their full size and the orbital cavities are only a little smaller than those of the adult. Growth of the skull is slow from the seventh year until the approach of puberty, when a second period of rapid skull enlargement occurs. This results in an increase of skull size in all directions, but it is especially marked in the frontal and facial regions, where it is associated with the development of the air sinuses.

The time of closure of the individual cranial sutures varies between individuals, but generally begins between the twentieth and thirtieth years. Usually the process commences in the sagittal and sphenofrontal sutures, but closure progresses very slowly and may not be complete in all the sutures until old age. The most striking feature of the old skull is the diminution in the size of the maxillae and

**FIG. 4-75.** Skull at birth, showing frontal and occipital fontanelles. Observe that the greatest width of the skull at this stage is at the level of the parietal tubers.

**Fig. 4-76.** Skull at birth, showing sphenoidal and mastoid fontanelles. Observe the small facial bones and the great difference in size between the facial and cranial vault bones in the neonatal skull.

mandible after the loss of the teeth and the absorption of the alveolar processes. This is associated with a marked reduction in the vertical (occlusal) measurement of the face and with an alteration in the condylar angles of the mandible (Fig. 4-83).

### *Sex Differences in the Skull*

Until the age of puberty there is little difference between the skull of the two sexes. The skull of an adult female is, as a rule, lighter and smaller, and its cranial capacity about 10% less than that of the male. Its walls are thinner and its muscular ridges less strongly marked. The glabella, superciliary arches, and mastoid processes are less prominent in females, and the corresponding air sinuses are smaller or may be rudimentary. The upper margin of the orbit is sharp, the forehead vertical, the frontal and parietal eminences prominent, and the vault somewhat flattened. The contour of the face is more rounded, the facial bones are smoother, and the maxillae and mandible and their contained teeth smaller. More of the morphological characteristics seen during the pre-puberty years are retained in the skull of the adult female than in that of the adult male. A well-marked male or female skull can easily be recognized as such, but in some cases the respective characteristics are so indistinct that the determination of the sex may be difficult or impossible.

### *Fractures of the Skull*

Consistent with the primary function of the skull, which is protection of the brain, is the fact that those portions of the skull that are most exposed to external violence are thicker than those that are shielded

from injury by overlying muscles. The skull-cap is thick and dense, whereas the temporal squamae, protected by the temporal muscles, and the inferior occipital fossae, shielded by the muscles at the back of the neck, are thin and fragile. The calvaria average about 5 to 6 mm in thickness, while the temporal squama is only 1 to 2 mm thick. The thickness of the skull at the glabella is slightly over 1 cm and at the external occipital protuberance between 1.5 and 2.0 cm. The skull is further protected by its elasticity, its rounded shape, and the fact that its structure contains a number of secondary elastic arches, each made up of a single bone.

The manner in which vibrations are transmitted through the bones of the skull is of importance as a protective mechanism, especially as far as the skull base is concerned. The vibrations resulting from a blow on the head are transmitted in a uniform manner in all directions to the top and sides of the skull, but at the base, due to the varying thickness and density of the bones, this is not so. In this latter region there are special buttresses that serve to carry the vibrations in certain definite directions. The laterally projecting ridge that is formed by the lesser and greater wings of the sphenoid bone and separates the anterior from the middle cranial fossae and, more posteriorly, the ridge that separates the middle from the posterior fossa form such buttresses. If any violence is applied to the cranial vault, the vibrations would be carried along these buttresses to the sella turcica, where they meet and form a center of resistance. Additionally, the subarachnoid cavity is somewhat dilated at this site and forms a cushion of fluid, helping to dissipate the vibrations. In like manner, when violence is applied to the base of the skull, as in falls when a person lands on his feet, the vibrations are carried backward through the occipital

crest, and forward through the basilar part of the occipital bone and body of the sphenoid up to the vault of the skull.

The calvaria and sides of the cranial cavity are formed by an inner layer of compact bone between which is the spongy diploic layer containing the vascular channels. Fractures involving the outer compact layer are relatively easy to identify; however, a blow on the head may be transmitted at times to the inner compact layer, resulting in a fracture of this layer with bony spicules and splinters without evidence of fracture to the outer compact layer.

Basal skull fractures of the **anterior cranial fossa** may involve the delicate cribriform plate of the ethmoid bone and/or the very thin orbital plate of the frontal bone. Such injury can cause lacerations of the dura mater with subsequent discharge of cerebrospinal fluid through the nose (cerebrospinal rhinorrhea) and injury to the olfactory nerves resulting in the loss of the sense of smell. Fractures of the orbital plate may result in hemorrhage into the orbital cavity, evidenced by subconjunctival discoloration and protrusion of the eyeball (exophthalmos).

Fractures of the bones of the **middle cranial fossa** are the most common basal skull fractures, probably because this region is weakened by the many foramina and canals. The petrous portion of the temporal bone is further weakened by containing the cavities of the inner ear. Fractures of the sphenoid bone frequently injure the meningeal vessels and may injure the internal carotid artery as well as the cavernous sinus. Injury might also be expected to the third, fourth, and sixth cranial nerves. Fractures in the middle fossa frequently involve the tegmen tympani (roof of the tympanic cavity). In these situations, if the tympanic membrane is ruptured, blood and cerebrospinal fluid can escape through the external auditory meatus. Fractures of the petrous portion of the temporal bone may injure the facial and vestibulocochlear nerves.

Fractures of the **posterior cranial fossa** may be exceedingly dangerous because cerebrospinal fluid and blood cannot escape, and even a seemingly small fracture might be fatal because of the pressure that develops on the vital centers in the brain stem. Fractures of the body of the sphenoid bone may paralyze the sixth cranial nerve, whereas fractures of the occipital bone may injure the hypoglossal nerve.

### Malformations of the Skull

One of the most common developmental malformations of the facial bones is **cleft palate**. The cleft may involve only the uvula or it may extend anteriorly through the soft palate and involve part or even all of the hard palate. In the latter instance, the cleft would extend as far forward as the incisive foramen. In the severest forms, the cleft extends through the alveolar process and continues between the premaxillary bone and the rest of the maxilla, that is between the lateral incisor and canine teeth. In some

instances, the cleft courses between the central and lateral incisor teeth, lending some support to the belief that the premaxillary bone develops from two centers and not one. The cleft may affect one or both sides. If it is bilateral, the central part is frequently displaced forward and remains united to the septum of the nose, the deficiency in the bony palate being complicated with a cleft lip.

## Individual Bones of the Skull

### THE MANDIBLE

The **mandible** (Figs. 4-77; 4-78) is the largest and strongest of the facial bones and extends from the chin in the midline to the two mandibular fossae laterally. It contains the lower teeth and consists of a horizontal portion, the **body**, and two perpendicular portions, the **rami**, which join the body nearly at right angles.

**BODY OF THE MANDIBLE.** The **body** (*corpus mandibulae*) is curved somewhat like a horseshoe, and has two surfaces and two borders.

The **external surface** of the body (Figs. 4-64; 4-77) is marked in the median line by a faint ridge, indicating the **symphysis menti** or line of fusion of the two separate halves of the mandible as seen in the fetus. This ridge divides inferiorly to enclose a triangular eminence, the **mental protuberance**, the base of which is depressed in the center but raised on each side to form the **mental tubercle**. On either side of the symphysis is a depression, the **incisive fossa**, which gives origin to the mentalis and a small portion of the orbicularis oris. Inferior to the second premolar tooth on each side is the **mental foramen**, for the passage of the mental vessels and nerve. Coursing posteriorly and upward from each mental tubercle is a faint ridge, the **oblique line**, which becomes continuous with the anterior border of the ramus. At its anterior end attaches the depressor labii inferioris and depressor anguli oris muscles. The platysma inserts near the inferior border (Fig. 4-77).

The **internal surface** of the body (Fig. 4-78) is concave and anteriorly presents two small bony projections on each side. Near the inferior part of the symphysis on each side is a laterally placed spine, termed the **mental spine**, which gives origin to the genioglossus. Immediately below these is a second pair of spines, or more frequently a median ridge or

FIG. 4-77. The left half of the mandible. Lateral aspect.

FIG. 4-78. The left half of the mandible. Medial aspect.

impression, for the origin of the geniohyoid muscles. On each side of the midline near the inferior margin of the symphysis is an oval depression for the attachment of the anterior belly of the digastric muscle. Extending posteriorly from the mental spine on each side of the symphysis is the **mylohyoid line**, which gives origin to the mylohyoid muscle. The posterior part of this line, near the alveolar margin, behind the third molar tooth, gives attachment to a small part of the superior pharyngeal constrictor, and to the pterygomandibular raphe. Superior to the anterior part of this line is the smooth, triangular **sublingual fossa** within which the sublingual gland rests, and inferior to the posterior part is the oval **submandibular fossa** which supports the submandibular gland.

The **superior border** or **alveolar part** of the mandibular body is hollowed into sockets for the reception of the sixteen teeth. The sockets, or **alveoli**, arranged sequentially in a curved bar of bone, the **alveolar arch**, vary in depth and size according to the teeth they contain. The sockets are separated by bony partitions, the **interalveolar septa**. The buccinator is attached to the outer lip of the superior border as far forward as the first molar tooth.

The **inferior border** is called the **base of the mandible**, and it is rounded, thicker anteriorly than behind, and at the point where it joins the lower border of the ramus there may be a shallow groove for the facial artery. The base of the mandible ends posteriorly at the mandibular angle, diagonal to the socket of the third molar tooth. From this point the ramus ascends in a nearly vertical manner.

**RAMUS OF THE MANDIBLE.** The **ramus** (*ramus mandibulae*) is quadrilateral in shape and has two surfaces, four borders, and two processes.

The **lateral surface** of the ramus (Fig. 4-77) is flat and marked by oblique ridges in its lower portion where the masseter muscle inserts. The **medial surface** (Fig. 4-72) presents near its middle the oblique **mandibular foramen** for the entrance of the inferior alveolar vessels and nerve into the **mandibular canal**. The margin of the mandibular foramen presents a prominent ridge, surmounted by a sharp spine anteriorly, the **lingula mandibulae**, to which attaches the sphenomandibular ligament. The **mylohyoid groove**

runs obliquely downward and forward from the foramen and lodges the mylohyoid vessels and nerve. Posterior to this groove is a roughened surface extending to the mandibular angle for the insertion of the medial pterygoid muscle. From the mandibular foramen and within the substance of the ramus, the **mandibular canal** courses obliquely downward and forward. After reaching the mandibular body, the canal continues horizontally forward, and is placed under the alveoli, communicating with them by small openings. At the level of the second premolar tooth, the canal splits, forming the **mental canal**, which courses upward and laterally to reach the **mental foramen**, and the incisive canal, which continues toward the symphysis, giving off two small channels to the incisor teeth. In the posterior two-thirds of the bone the mandibular canal is situated near the internal surface of the mandible, whereas in the anterior third the canal is nearer its external surface. Through the canal courses the inferior alveolar vessels and nerve, from which branches are distributed to the lower teeth.

The **inferior border** of the ramus is thick and straight and joins the posterior border at the **angle of the mandible**. The mandibular angle, which measures about 120 degrees, may be either a bit inverted or everted and serves for attachment on its outer aspect of the masseter and on its inner aspect of the medial pterygoid muscle. Between these two muscles, the stylomandibular ligament attaches to the angle. The **posterior border** is thick, smooth, and rounded. It extends from the condylar process above to the mandibular angle below and is covered by the parotid gland. The **anterior border** is continuous above with the **coronoid process** and below with the oblique line. The **superior border** is thin, and is surmounted by the coronoid process anteriorly and the condylar process posteriorly, separated by the mandibular notch.

The **coronoid process** (*processus coronoideus*; Fig. 4-77) is a thin, triangular eminence, and it varies in shape and size. Its anterior border is convex and is continuous with the anterior border of the ramus; its posterior border is concave and forms the anterior boundary of the mandibular incisure (notch). Along its entire medial surface inserts the temporalis muscle, the insertion

extending along the entire rim of the process and over onto the lateral surface. The medial surface is also marked by a bony ridge, which begins near the apex of the process and runs downward and forward to the inner side of the last molar tooth.

The **condylar process** (*processus condylaris*) is thicker than the coronoid, and consists of two portions: the articular portion, called the **head** (*condyle*), and the constricted portion that supports it, the **neck**. The head presents an oval surface covered with fibrocartilage for articulation with the temporal bone at the mandibular fossa. Interposed between the two articular surfaces is the articular disc of the temporomandibular joint. In a living subject the head can be manipulated about 1 cm anterior to the tragus. With the jaw closed it lies totally within the mandibular fossa. When the jaw opens, the head and disc glide forward within the joint capsule, leaving a small depression in front of the tragus. At the lateral extremity of the head is a small tubercle for the attachment of the lateral (temporomandibular) ligament. The **neck** is flattened and strengthened by ridges that descend from the anterior and lateral parts of the head. Its posterior surface is convex; its anterior presents a depression, the **pterygoid fovea**, for the insertion of the lateral pterygoid muscle. On the medial surface of the neck just posterior to the insertion of the lateral pterygoid is a blunt crest called the **dental trajectory** or the **mandibular crest**.

The **mandibular incisure** or **notch**, separating the two processes, is a deep semilunar depression, and is crossed by the masseteric vessels and nerve.

**OSSIFICATION.** The mandible is ossified in the fibrous membrane covering the outer surface of the right and left **Meckel's cartilages**. These are the cartilaginous bars of the first branchial arch (**mandibular arch**). Their proximal or cranial ends are connected with the ear capsules, and their distal extremities are joined at the symphysis menti by mesodermal tissue. From the proximal end of each cartilage, the *malleus* and *incus*, two of the bones of the middle ear, are developed. The next succeeding portion, as far as the lingula, is replaced by fibrous tissue, which persists to form the *sphenomandibular ligament*. Between the lingula and the canine tooth the cartilage disappears; the remaining portion adjacent to the incisor teeth becomes ossified and incorporated into this part of the mandible.

Ossification takes place in the membrane covering the outer surface of the ventral end of Meckel's carti-

lage (Figs. 4-79 to 4-82). Each half of the mandible is formed from a single center, which appears near the mental foramen at about the sixth week of fetal life. By the tenth week the portion of Meckel's cartilage that lies adjacent to the incisor teeth is surrounded and invaded by the membranous bone. Somewhat later, accessory cartilaginous nuclei make their appearance—as a wedge-shaped nucleus in the condylar process which extends downward through the ramus (Fig. 4-82), as a small strip along the anterior border of the coronoid process (Fig. 4-82), and as smaller cartilaginous nuclei in the front part of both alveolar walls and along the front of the lower border of the bone (Fig. 4-83). These accessory nuclei possess no separate ossific centers, but are invaded by the surrounding membranous bone and undergo absorption. The inner alveolar border, usually described as arising from a separate ossific center (*splenic center*), is formed in the human mandible by an ingrowth from the main mass of the bone. At birth the bone consists of two parts, united anteriorly by the fibrous symphysis menti which ossifies during the first year.

**ARTICULATIONS.** The mandible articulates with the two temporal bones.

**CHANGES PRODUCED BY AGE.** At birth (Fig. 4-83, A) the body of the bone is a mere shell, containing the sockets of the two incisors, the canine, and the two deciduous molar teeth, imperfectly partitioned from one another. The mandibular canal is large and runs near the lower border of the bone, and the mental foramen opens beneath the socket of the first

Fig. 4-79. Mandible of human embryo 24 mm long. Outer aspect. Cartilage is in blue, bone in yellow. (From model by Low.)

Fig. 4-80. Mandible of human embryo 24 mm long. Inner aspect. Cartilage is in blue, bone in yellow. (From model by Low.)

deciduous molar tooth. The mandibular angle is obtuse (175 degrees), and the condylar process is nearly in line with the body. The coronoid process is comparatively large and projects above the level of the head of the mandible.

**After birth** (Fig. 4-83, *B*) the two segments of the bone become joined from below upward at the symphysis in the first year (Fig. 4-83, *A*), but a trace of separation may be visible in the beginning of the second year near the alveolar margin. The entire length of the mandibular body becomes elongated, but more especially posterior to the mental foramen, which provides space for the three additional teeth developed in this part. The depth of the body increases due to enlargement of the alveolar part. This allows room for the roots of the teeth, and results in the thickening of the portion below the oblique line, which enables the jaw to withstand the powerful action of the masticatory muscles. The alveolar portion, however, becomes the deeper of the two parts, and consequently the largest portion of the mandibular body lies above the oblique line. The mandibular canal, after *second dentition* (Fig. 4-83, *C*), is situated just above the level of the mylohyoid line and the mental foramen occupies the more adult position. The mandibular angle diminishes due to the separation of the jaws by the teeth, and by the fourth year it is 140 degrees.

**In the adult** (Fig. 4-83, *D*) the alveolar portion and the portion below the oblique line are usually of equal depth. The mental foramen opens midway between the upper and lower borders of the bone, and the mandibular canal runs nearly parallel with the mylohyoid line. The ramus is almost vertical in direction, and the mandibular angle measures about 120 degrees.

**In old age** (Fig. 4-83, *E*) the mandible becomes greatly reduced in size because the alveolar process is absorbed after the loss of the teeth, leaving the chief bulk of the bone below the oblique line. The mandibular canal with the mental foramen opening from it becomes positioned close to the alveolar border. The angle widens once more, measuring about 140 degrees, and the neck of the condylar process becomes oriented slightly backward.

### HYOID BONE

The **hyoid bone** (os hyoideum; Fig. 4-84), named from its resemblance to the Greek letter U, is suspended from the tips of the styloid processes of the temporal bones by the stylohyoid ligaments. It is located in the anterior part of the neck between the chin and the larynx, and is composed of five por-

**FIG. 4-81.** Mandible of human embryo 95 mm long. Outer aspect. Nuclei of accessory cartilages stippled. Cartilage is in blue, bone in yellow. (From model by Low.)

**FIG. 4-83.** The mandible at different periods of life. Left lateral aspect.

tions: a body, two greater cornua, and two lesser cornua.

The **body** (*corpus ossis hyoidei*) or central part is quadrilateral in shape and placed transversely across the midline of the neck. Its **ventral surface** (Fig. 4-84) is convex and is directed forward and somewhat cranially. Its upper half is crossed by a well-marked transverse ridge, and in many cases a vertical median ridge divides it into two lateral

halves. The geniohyoid muscle is inserted into the greater part of the ventral surface, both above and below the transverse ridge. A portion of the origin of the hyoglossus muscle encroaches upon the lateral margin of the geniohyoid attachment. Below the transverse ridge are inserted the mylohyoid, sternohyoid, and omohyoid muscles. The **dorsal surface** is smooth and concave, and is directed somewhat caudally, being sepa-

**FIG. 4-84.** Hyoid bone. Anterior surface viewed from above.

rated from the epiglottis by the thyrohyoid membrane, an intervening bursa, and a quantity of loose areolar tissue. The **superior border** is rounded and gives attachment to the thyrohyoid membrane and some aponeurotic fibers of the genioglossus. The **inferior border** receives the insertion of the sternohyoid muscle medially, the omohyoid laterally, and occasionally the medial portion of the thyrohyoid. It also gives attachment to the levator glandulae thyroideae, when this muscle is present. In early life the lateral borders of the body are connected by cartilage to the greater cornua, but after middle life this union is osseous.

The two **greater cornua** (*cornua majora*) project dorsally from the lateral border of the body (Fig. 4-84). Each cornu, or horn, is flattened and becomes more slender posteriorly, ending in a tubercle to which is fixed the lateral thyrohyoid ligament. The greater cornua can be palpated above the lateral aspects of the thyroid cartilage and their cranial surfaces are rough near the lateral borders for muscular attachments. The most extensive attachments are the origins of the hyoglossus and constrictor pharyngis medius which stretch along the whole length of the horn. The digastric and stylohyoid muscles have small insertions near the junction of the horn with the body. The digastric is attached by a small connective tissue loop through which its tendon courses. The thyrohyoid membrane is attached along the medial border of each horn and the thyrohyoid muscle is attached anteriorly along the lateral border.

The two **lesser horns** (*cornua minora*) are

small, conical eminences, each attached by its base to the angle of junction between the body and the greater horn (Fig. 4-84). The lesser horn is connected to the body of the hyoid by fibrous tissue, and occasionally to the greater horn by a distinct synovial joint, which may either persist throughout life, or become ankylosed.

The lesser horn is situated in line with the transverse ridge on the body and appears to be in morphological continuation to it. The stylohyoid ligament is attached to the apex of the lesser horn and the chondroglossus arises from the medial side of its base.

**DEVELOPMENT AND OSSIFICATION.** The greater horns and much of the body of the hyoid are derived embryologically from the third visceral arch cartilage. A portion of the body, the lesser horns, and the stylohyoid ligaments to which they are attached are derived from the second or hyoid arch.

The hyoid is ossified from six centers: two for the body, and one for each horn. Ossification commences in the greater horns toward the end of fetal life, in the body shortly afterward, and in the lesser cornua during the first or second year after birth.

#### OCCIPITAL BONE

The **occipital bone** (*os occipitale*), which forms most of the posterior aspect of the skull as well as part of its base, is trapezoid in shape and internally concave in a cup-like manner (Figs. 4-85; 4-86). It is pierced by a large oval aperture, the **foramen magnum**, through which the cranial cavity communicates with the vertebral canal. The curved, expanded plate posterior to the foramen magnum is named the **squama**; the thick, somewhat quadrilateral portion anterior to the foramen is called the **basilar part**, and on each side of the foramen is the **lateral portion**.

**THE SQUAMA.** The **squama** (*squama occipitalis*), situated above and bordering the posterior part of the foramen magnum, is curved and rounded from above downward and from side to side. The **external surface** is convex and, midway between the summit of the bone and the foramen magnum, presents a bony prominence, the **external occipital protuberance** (Fig. 4-85). Extending lateralward from this on each side are two curved lines, one a little above the other. The more superior, often faintly marked, is named the

FIG. 4-85. Occipital bone. Outer surface as visualized from below.

highest nuchal line, and to it the galea aponeurotica is attached. The lower is termed the **superior nuchal line**. That part of the squama that lies above the highest nuchal line is named the **planum occipitale**, and is covered by the occipital belly of the occipitofrontalis muscle; that below, termed the **planum nuchale**, is rough and irregular for the attachment of several muscles. From the external occipital protuberance a ridge or crest, **external occipital crest**, which is also called the **median nuchal line**, runs to the foramen magnum and affords attachment to the ligamentum nuchae. Midway along the crest on each side, the **inferior nuchal line** courses laterally from the crest across the planum nuchale, dividing it approximately in half. The muscles attached to the external surface of the squama include the origins of the occipital belly of occipitofrontalis and trapezius along the superior nuchal line and the insertions of the sternocleidomastoid and the splenius capitis laterally also along this line. Into the surface between the superior and inferior nuchal lines are inserted the semispinalis capitis and

obliquus capitis superior. Along the inferior nuchal line and below it are inserted the recti capitis posteriores major and minor. The posterior atlanto-occipital membrane is attached around the posterolateral part of the foramen magnum, just outside its margin.

The **internal surface** of the occipital bone is deeply concave and divided into four fossae by bony ridges which cross each other and along which course venous sinuses. The two superior fossae are triangular and lodge the occipital lobes of the cerebrum, while the inferior two are quadrilateral and accommodate the hemispheres of the cerebellum (Fig. 4-86). At the point of intersection of the bony ridges is the **eminencia cruciata**, on the peak of which is the **internal occipital protuberance**. From this protuberance one ridge courses superiorly to the upper angle of the bone, and on one side of it (generally the right) is a deep groove, the **sagittal sulcus**, which lodges the posterior part of the superior sagittal sinus. Along the margins of this sulcus the falx cerebri is attached. The ridge coursing inferiorly from the internal

FIG. 4-86. Occipital bone. Inner surface as visualized from above.

occipital protuberance is named the **internal occipital crest**, and it bifurcates near the foramen magnum, giving attachment to the falx cerebelli. In the attached margin of this falx is the *occipital sinus*, which is sometimes duplicated. Along the internal occipital crest a small depression, called the *vermian fossa* and occupied by the vermis of the cerebellum, is sometimes distinguishable. Transverse grooves extend on each side from the internal occipital protuberance to the lateral angles of the bone. They accommodate the *transverse sinuses*, and the margins of the grooves give attachment to the tentorium cerebelli. The groove on the right side is usually larger than that on the left and is continuous with that for the superior sagittal sinus. Exceptions to this description exist, however, since the left may be larger than the right or the two may be almost equal in size. The point of junction between the superior sagittal and transverse sinuses

is named the *confluence of the sinuses*, and its position is indicated by a depression situated on one side or the other of the protuberance.

**LATERAL PARTS.** The **lateral parts** (*pars lateralis*) of the occipital bone are situated at the sides of the foramen magnum. These regions of the bone are sometimes called the **condylar parts** because on their **inferior surfaces** are the **occipital condyles** for articulation with the superior facets of the atlas (Fig. 4-85). The condyles are oval in shape, with their anterior extremities encroaching on the basilar portion of the bone, and their posterior extremities diverging toward the middle of the foramen magnum. The articular surface of the condyle is convex, and it is directed laterally and downward. To its margin is attached the capsule of the atlanto-occipital articulation, and on the medial side of each condyle is a rough impression or tubercle for the alar ligament. At

the base of the condyle the bone is tunnelled by a short canal, the **hypoglossal canal**, through which exits the hypoglossal or twelfth cranial nerve from the cranial cavity. Additionally, a meningeal branch of the ascending pharyngeal artery enters the cranial cavity through this canal, which actually may be partially or completely divided into two canals by a spicule of bone. Posterior to each condyle is a depression, the **condyloid fossa**, into which the posterior margin of the superior facet of the atlas is received when the head is extended backward. The floor of this fossa is sometimes perforated by the **condyloid canal**, through which an emissary vein passes. Extending laterally from the posterior half of the condyle is a quadrilateral plate of bone, the **jugular process**. Anteriorly this process is indented by the **jugular notch** (Fig. 4-85), which, in the articulated skull, forms the posterior part of the **jugular foramen**. The jugular notch may also be divided into two indentations by a bony spicule, the **intrajugular process**, which projects laterally above the hypoglossal canal. The inferior surface of the jugular process is roughened and affords insertion to the rectus capitis lateralis muscle and attachment of the lateral atlanto-occipital ligament. From this surface an eminence, the **paramastoid process**, sometimes projects downward and may be of sufficient length to reach and articulate with the transverse process of the atlas. Laterally the jugular process also presents a roughened triangular area, which is joined to the jugular surface of the temporal bone by a plate of cartilage that tends to ossify after the age of twenty-five.

The **superior surface** of the lateral part presents an oval eminence, the **jugular tubercle**, which overlies the hypoglossal canal and is frequently crossed by an oblique groove for the glossopharyngeal, vagus, and accessory nerves. On the superior surface of the jugular process is a deep groove that curves medially and anteriorly and is continuous with the jugular notch. This groove lodges the continuation of the transverse sinus, the terminal portion of which is called the sigmoid sinus. Close to the medial margin of the groove opens the orifice of the condyloid canal.

**BASILAR PART.** The **basilar part** (*pars basilaris*) of the occipital bone is virtually quadrilateral in shape and extends anteriorly and superiorly from the foramen magnum

(Fig. 4-85). In the young skull the basilar part is joined to the body of the sphenoid by a plate of cartilage (Fig. 4-87). By the twenty-fifth year, however, this cartilaginous plate is ossified, and the occipital and sphenoid bones become fused at this site.

On its **inferior surface**, about 1 cm anterior to the foramen magnum, is the **pharyngeal tubercle**, which gives attachment to the fibrous raphe of the pharynx. On each side of the midline, the longus capitis and rectus capitis anterior muscles are inserted, and immediately anterior to the foramen magnum the anterior atlanto-occipital membrane is attached.

The **superior surface** presents a broad, shallow groove upon which rests the lower pons and medulla oblongata of the brainstem. Near the margin of the foramen magnum is attached the tectorial membrane as well as the apical dental ligament. On the lateral margins of this surface are faint grooves for the inferior petrosal sinuses.

The **foramen magnum** is a large oval aperture, wider behind than in front, with its long diameter anteroposterior. It transmits the medulla oblongata and its membranes, the accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, the tectorial membrane, and alar ligaments.

The **superior angle** of the occipital bone (Fig. 4-86) articulates with the occipital an-

**Fig. 4-87.** Occipital bone at birth. Observe that the neonatal occipital bone consists of four ossified parts (squama, two lateral parts and the basilar part) interconnected by cartilaginous strips.

gles of the parietal bones and, in the fetal skull, corresponds in position with the posterior fontanelle (Fig. 4-75). The **inferior angle** is fused with the body of the sphenoid. The **lateral angles**, located at the extremities of the grooves for the transverse sinuses, are received into the interval between the mastoid angle of the parietal and the mastoid part of the temporal bone.

The **lambdoid borders** (*margo lambdoideus*) extend from the superior to the lateral angles: they are deeply serrated for articulation with the occipital borders of the parietals, and form by this union the lambdoidal suture. The **mastoid borders** (*margo mastoideus*) extend from the lateral angles to the inferior angle. The posterior half of each mastoid border articulates with the mastoid portion of the corresponding temporal, while the anterior half articulates with the petrous part of the same bone. Between these two parts of the mastoid border is the jugular process, the notch on the anterior surface of which forms the posterior part of the jugular foramen.

**STRUCTURE.** The occipital, like the other cranial bones, consists of two compact lamellae, called the outer and inner tables, between which is the cancellous tissue or diploë. The bone is especially thick at the ridges, protuberances, condyles, and anterior region of the basilar part. In the inferior fossae, within which rests the cerebellum, the bone is thin, semitransparent, and destitute of diploë.

**OSSIFICATION** (Fig. 4-87). The portion of the squama above the nuchal lines, the *planum occipitale*, is developed in membrane, and may remain separate throughout life, in which case it constitutes the *interparietal bone*. The rest of the bone is developed in cartilage. Ossification commences in the *planum occipitale* from two centers which appear near the midline at about the eighth week of fetal life. Two other centers appear at some distance from the midline at about the third fetal month. The *planum nuchale* of the squama, located below the highest nuchal lines, is ossified from two centers, which appear in the cartilage at about the seventh week of fetal life and soon unite to form a single center. Union of the upper and lower portions of the squama takes place in the third month of fetal life. Each of the *lateral parts* begins to ossify from a single center also during the eighth week of fetal life. The *basilar portion* is ossified from either one or two centers, which appear at about the sixth week of prenatal life.

At birth, the occipital bone consists of four ossified pieces—the squama, two lateral parts, and the basilar part—united by cartilaginous strips (Fig.

4-87). The lines of union between the portions of the squama are also still evident. About the fourth year the squama and the two lateral portions unite, and by about the sixth year the bone consists of a single piece. Between the eighteenth and twenty-fifth years the synchondrosis between the occipital and sphenoid becomes united, forming a single bone.

**ARTICULATIONS.** The occipital bone articulates with six other bones: the two parietals, the two temporals, the sphenoid, and the atlas.

## PARIETAL BONE

The **parietal bones** (*os parietale*), by their union, form the sides and roof of the cranium. Each bone is irregularly quadrilateral in shape and presents two surfaces, four borders, and four angles.

**SURFACES.** The **external surface** (Fig. 4-88) is convex, smooth, and marked near the center by the mound-like **parietal eminence** (*tuber parietale*), an elevation of even greater convexity and the site at which ossification commences in the fetus. Crossing the middle of the bone in an arched direction are two curved lines, the **superior** and **inferior temporal lines**. The former gives attachment to the temporal fascia, and the latter indicates the upper limit of the muscular origin of the temporalis. Above these lines the bone is covered by the galea aponeurotica of the scalp, while below the lines the parietal bone forms the medial boundary of the temporal fossa and also lends origin to the temporalis. Close to the upper or sagittal border posteriorly is the **parietal foramen**, which transmits a vein to the superior sagittal sinus and, sometimes, a small branch of the occipital artery. The foramen is not constantly present, and its size varies considerably.

The **internal surface** (Fig. 4-89) is concave and presents depressions corresponding to the cerebral convolutions, and numerous furrows for the ramifications of the middle meningeal vessels. These vascular furrows course upward and backward from the anteroinferior sphenoidal angle and from the central and posterior part of the squamous border. Along the superior edge of the bone is a shallow groove, which combines with that of the opposite parietal to form the midline **sulcus for the superior sagittal sinus**. The edges of the sulcus afford attachment to the falx cerebri. Near the groove are several depressions or pits, **granular foveolae**, best marked in the skulls of old persons, which

**FIG. 4-88.** Left parietal bone, external surface. Observe the serrated borders of the parietal bone. These contribute to the formation of the coronal suture in front, the sagittal suture above, the lambdoidal suture behind, and the squamosal suture below. Additionally, the squamosal border of the parietal bone contributes to the sphenoparietal suture anteriorly and the parietomastoid suture posteriorly.

contain the **arachnoid granulations** (*Pacchionian bodies*). In the groove is the internal orifice of the parietal foramen.

**BORDERS.** The **sagittal border** is the longest and thickest and its deeply serrated edge articulates with the same border of the opposite parietal bone, thereby forming the sagittal suture. The **squamosal border** is the inferior border of the parietal bone and it is divided into three parts: of these, the anterior is thin, bevelled externally, and pointed, and is overlapped by the tip of the great wing of the sphenoid; the middle portion is arched and also bevelled externally, and is overlapped by the squama of the temporal bone; the posterior part is thick and serrated for articulation with the mastoid portion of the temporal bone. The **frontal border** is deeply serrated and is externally bevelled above and internally bevelled below. This border articulates with the frontal bone, forming one-half of the coronal suture. The

**occipital border** is deeply denticulated and forms one-half of the lambdoidal suture by articulating with the occipital bone.

**ANGLES.** The **frontal angle** is practically a right angle. It is the anterosuperior angle of the bone and corresponds with the site of junction of the sagittal and coronal sutures, the **bregma**. In the fetal skull and for about a year and a half after birth, this region is not ossified and is called the **anterior fontanelle** (Figs. 4-75; 4-76). The **sphenoidal angle**, located anteroinferiorly on the parietal bone, is thin and acute, and is received into the interval between the frontal bone and the great wing of the sphenoid. On the side of the skull in the vicinity of the sphenoidal angle there are four bones in proximity: the parietal, sphenoid, temporal, and frontal. This site is called the **pterion**. The inner surface of the bone near the sphenoidal angle is marked by a deep groove, which sometimes forms a canal for the frontal branch of the

**FIG. 4-89.** Left parietal bone, internal surface. Note the vascular grooves not only for the meningeal vessels but also for the superior sagittal sinus and the sigmoid sinus. It is at the mastoid angle that the transverse sinus becomes the sigmoid sinus.

middle meningeal artery. The **occipital angle** is located posterosuperiorly on the bone and is more rounded than the previous two. It corresponds with the intersection of the sagittal and lambdoid sutures, the **lambda**. In the newborn skull this site is yet to ossify and is called the **posterior fontanelle** (Fig. 4-75). The thick and truncated **mastoid angle** is located posteroinferiorly. It articulates with the occipital bone and with the mastoid portion of the temporal. On its inner surface is found a broad, shallow groove which lodges the transition site of the transverse sinus, beyond which it is known as the sigmoid sinus. The point where this angle meets with the mastoid part of the temporal bone is named the **asterion**.

**OSSIFICATION.** The parietal bone ossifies intramembranously from two centers, one above the other, which appear at the parietal eminence about the eighth week of fetal life. The two centers fuse during the third month and ossification gradually extends in a radial manner toward the margins of the bone. The angles are consequently the last sites to be ossified and it is here that the fontanelles exist. Occasionally the parietal bone is divided into two

parts by an anteroposterior suture caused by a failure of the two primary ossification sites to fuse.

**ARTICULATIONS.** The parietal usually articulates with five bones: the opposite parietal, the occipital, frontal, temporal, and sphenoid. At times the parietal bone does not articulate with the sphenoid. In these instances the frontal bone reaches posteriorly as far as the squama of the temporal without the greater wing of the sphenoid achieving the squamosal border of the parietal bone.

### FRONTAL BONE

The **frontal bone** (*os frontale*) encases the cranial cavity anteriorly and is shaped as an externally convex shell. It consists of two portions: the **squama**, which is vertical and forms the osseous convexity of the forehead, and the **orbital portion**, which is horizontal and enters into the formation of the roofs of the orbital and nasal cavities.

**SQUAMA OR VERTICAL PART** (*squama frontalis*). The **external surface** (Fig. 4-90) of the squama of the frontal bone is convex and in the midline usually retains evidence of the **frontal or metopic suture**. In infancy this

FIG. 4-90. Frontal bone. Outer surface as viewed from anterior aspect.

suture separates the two lateral halves of the bone, a condition that may persist throughout life. On each side of this suture, about 3 cm superior to the supraorbital margin, is a rounded elevation, the **frontal eminence** (*tuber frontale*). These eminences vary in size, are occasionally asymmetrical, and are especially prominent in young skulls. Inferior to the frontal eminences, and separated from them by a shallow groove, are the **superciliary arches**, which are prominent medially and joined to one another by a smooth elevation named the **glabella**. These curved arches are larger in males than in females, and to some extent their degree of prominence depends on the size of the frontal air sinuses. Beneath each superciliary arch is a curved and prominent margin, the **supraorbital margin**, which forms the boundary of the orbit and separates the squama from the orbital portion of the bone. The lateral part of this margin is sharp and prominent, affording protection to the eye, and its medial part is rounded. Along the margin, a third of the distance from its medial end, is the **supraorbital notch** or **foramen**, which transmits the supraorbital ves-

sels and nerve. A small aperture in the notch transmits a vein from the diploë to join the supraorbital vein. The supraorbital margin ends laterally in the **zygomatic process**, which is strong and prominent and articulates with the zygomatic bone. Coursing upward and backward from the zygomatic process is the **temporal line**, which then divides into upper and lower temporal lines, continuous in the articulated skull with the corresponding lines on the parietal bone.

Between the supraorbital margins the squama projects inferiorly to a level even farther than the zygomatic process. This portion of the frontal bone is the **nasal part**, and it presents a rough, uneven interval, the **nasal notch**, which articulates with the nasal bone, the frontal process of the maxilla, and the lacrimal. The center of the frontonasal suture is a craniometric point called the **nasion**. From the center of the notch, the nasal part projects inferiorly beneath the nasal bones and the frontal processes of the maxillae to support the bridge of the nose. The nasal part ends inferiorly as the sharp **nasal spine**, on each side of which is a small grooved nasal surface that enters into the

formation of the roof of the corresponding nasal cavity (Fig. 4-91). The spine forms a small portion of the nasal septum (Figs. 4-71; 4-72) and articulates anteriorly with the crest of the nasal bones and with the perpendicular plate of the ethmoid posteriorly.

The **internal surface** (Fig. 4-91) of the squama is concave and presents in the midline a vertical groove, the **sulcus for the superior sagittal sinus**, the edges of which unite below to form a ridge, the **frontal crest**. The sulcus lodges the anterior part of the superior sagittal sinus, while its margins and the crest afford attachment to the falx cerebri. The crest ends in a small notch, which is converted into the **foramen cecum** by articulation with the ethmoid bone. This foramen varies in size and is frequently closed; when open, it transmits a vein from the roof of the nasal cavity to the superior sagittal sinus. On each side of the midline the bone presents depressions for convolutions of the frontal lobes of the brain, and numerous small pits,

the **granular foveolae**, for the arachnoid granulations.

The **parietal border** of the squama of the frontal bone is thick, strongly serrated, and bevelled. It articulates posteriorly and laterally with the parietal bones. This border is continued below into a triangular, rough surface which articulates with the great wing of the sphenoid.

**ORBITAL OR HORIZONTAL PART** (*pars orbitalis*). The orbital portion of the frontal bone consists of two smooth **orbital plates** which form most of the roofs of the orbits. They are separated from one another by a gap in the midline, the **ethmoidal notch**. The concave **inferior surface** (Fig. 4-91) presents a shallow depression laterally, the **fossa for the lacrimal gland**. Medially, near the nasal part, is a depression, the **fovea trochlearis**, or occasionally a small trochlear spine, for the attachment of the cartilaginous pulley of the superior oblique muscle of the eye. The superior (or intracranial) surface is convex

**FIG. 4-91.** Frontal bone. Inner surface as viewed from its inferior aspect. Observe that on the left side of the figure is accentuated the lines of articulation of the frontal bone. These are with the parietal, zygomatic, and greater wing of the sphenoid bone laterally and the small wing of the sphenoid, ethmoid, lacrimal, maxillary, and nasal bones medially.

and marked by depressions for gyri on the orbital surface of the frontal lobes of the brain, and by faint grooves for the meningeal branches of the ethmoidal vessels. The **posterior borders of the orbital plates** are thin and serrated, and articulate with the small wings of the sphenoid.

The **ethmoidal notch** that separates the two orbital plates is filled, in the articulated skull, by the cribriform plate of the ethmoid. The margins of the notch are indented by several air cells which, when united with corresponding cells on the superior surface of the ethmoid, form the ethmoidal air cells. Two grooves cross these edges transversely and are converted, by articulation with the ethmoid bone, into the **anterior and posterior ethmoidal canals**, which open on the medial wall of the orbit and transmit the anterior and posterior ethmoidal vessels and nerves.

The **frontal air sinuses** open on both sides of the frontal spine and anterior to the ethmoid air cells and ethmoid notch. The sinuses are two irregularly shaped hollow cavities that extend for a variable distance between the two tables of the skull. They are separated from one another by a thin bony septum, which often deviates to one side or the other, with the result that the sinuses are rarely symmetrical. They vary in size and are larger in men than in women. The frontal sinuses are lined by mucous membrane, and communicate with the nasal cavity by means of a passage called the **frontonasal duct**, which opens into the middle meatus of the corresponding nasal cavity.

**STRUCTURE.** The squama and the zygomatic processes are very thick, consisting of cancellous bone contained between two compact laminae. The cancellous bone is absent in the regions occupied by the frontal air sinuses. The orbital portion is thin, translucent, and composed entirely of compact bone, explaining the facility with which instruments can penetrate the cranium through this part of the orbit.

**OSSIFICATION** (Fig. 4-92). The frontal bone is ossified in membrane from two primary centers. These appear toward the end of the second month of fetal life, one above each superciliary arch. From each of these centers ossification extends upward to form the corresponding half of the squama, inferiorly to form the nasal part, and backward to form the orbital plate. At birth the bone consists of two pieces, separated by the **frontal or metopic suture**, which is usually fused by the eighth year except at its lower part. Occasionally it persists throughout

**FIG. 4-92.** Frontal bone at birth. The neonatal frontal bone consists of two halves between which is found the frontal or metopic suture.

life. During childhood and after the metopic suture has united (between the tenth and twelfth years), secondary ossification centers appear at the lower end of the suture to form the nasal spine of the frontal bone. It is generally maintained that development of the frontal sinuses has begun by the end of the first year. The frontal sinuses have developed considerably by the seventh or eighth year, but do not attain their maximum size until adulthood.

**ARTICULATIONS.** The frontal bone articulates with twelve bones: the sphenoid, the ethmoid, the two parietals, the two nasals, the two maxillae, the two lacrimals, and the two zygomatics (Fig. 4-91).

#### TEMPORAL BONE

The **temporal bone** (*os temporale*; Figs. 4-93 to 4-97) is situated at the lateral aspect and base of the skull. It contains the peripheral receptors for both the special sense of hearing and the maintenance of equilibrium or vestibular function. Developmentally, the temporal bone forms from a fusion of three parts: the flattened **squamous** portion; the hard **petromastoid** part, which encases the membranous labyrinth and its receptors; and the curved, ring-like **tympanic** part, interposed between the previous two (Fig. 4-98). Additionally, the **styloid process**, derived from the cartilage of the second visceral arch, unites with the inferior aspect of the bone.

**THE SQUAMA.** The squamous part is thin, translucent, and scale-like, and forms the anterior and superior part of the bone. Its **temporal or external surface** (Fig. 4-93) is smooth and convex, forms part of the temporal fossa, and affords attachment to the

FIG. 4-93. The left temporal bone. External aspect.

FIG. 4-94. Left temporal bone. The cerebral or internal surface.

**FIG. 4-95.** Coronal section of right temporal bone which has been opened to display the mastoid antrum and cells as well as the roof and medial wall of the tympanic cavity.

temporalis muscle. The curved **temporal line** limits the origin of the temporalis muscle. The boundary between the squama and the mastoid process of the bone lies about 1 cm below this line. Superior to the external acoustic meatus, the external surface presents a vertically coursing **groove for the middle temporal artery**.

The **zygomatic process** is a narrow arch of bone that projects forward from the inferior part of the squama. Its thin superior border is sharp and serves for the attachment of the temporal fascia; its inferior border is somewhat thicker and arched, and affords attachment to some fibers of the masseter muscle. The lateral surface is convex and lies just beneath the skin, while the medial surface is concave and also allows origin to the masseter muscle. The anterior end is deeply serrated and articulates with the zygomatic bone. The posterior end arises from the squama by two roots. The **posterior root**, a prolongation of the upper border, courses above the opening of the external acoustic meatus and is continuous with the temporal line. The **anterior root** is continuous with the inferior border. It is short, broad, and strong, and is directed medialward, ending in a

rounded eminence, the **articular tubercle**. This tubercle forms the anterior boundary of the **mandibular fossa**. In the intact body the tubercle is covered with cartilage and the fossa receives the condyle of the mandible to form the temporomandibular joint. Between the posterior wall of the external acoustic meatus and the posterior root of the zygomatic process is an area called the **suprameatal triangle**, through which an instrument may be pushed into the tympanic antrum.

The **mandibular fossa (glenoid fossa)** is bounded anteriorly by the articular tubercle, and posteriorly by the bony rim surrounding the external acoustic meatus. The fossa is ovoid in shape and divided into two parts by a narrow slit, the **tympanosquamosal fissure**, which, when traced medially, becomes continuous with the **petrotympanic fissure**. The anterior part of the fossa, formed by the squama, is smooth and covered with cartilage for articulation with the condyle of the mandible. Behind this part of the fossa is a small conical eminence, the **postglenoid process**. This process is representative of a prominent tubercle, seen in some mammals, which projects behind the condyle of the

**FIG. 4-96.** The right temporal bone has been opened to reveal the medial wall of the tympanic cavity. Observe that the facial canal and semicircular canals have also been opened. Note that the course of the facial canal in the petrous temporal bone is at first directed laterally (toward the middle ear), then posteriorly, and finally inferiorly. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban and Schwarzenberg, 1975.)

mandible and prevents its backward displacement. The posterior part of the mandibular fossa is formed by the tympanic part of the bone and is nonarticular. The petrotympanic fissure leads into the middle ear or tympanic cavity, where it lodges the anterior ligament of the malleus and transmits the anterior tympanic branch of the maxillary artery. The chorda tympani nerve passes through a canal (**anterior canaliculus of chorda tympani**), which is separated from the anterior edge of the petrotympanic fissure by a thin scale of bone and situated on the lateral side of the auditory tube in the angle between the squama and the petrous portion of the temporal bone.

The **cerebral** or **internal surface** of the squama (Fig. 4-94) presents depressions corresponding to the convolutions of the temporal lobe of the brain, and grooves for the branches of the middle meningeal vessels. The **superior border** is thin, bevelled at the expense of the internal table, and overlaps the squamous border of the parietal bone, forming with it the squamosal suture. Posteriorly, the superior border forms an angle,

the **parietal notch**, with the mastoid portion of the bone. The **antero-inferior border** is thick, serrated, and bevelled at the expense of the inner table above and of the outer below. It articulates with the great wing of the sphenoid.

**PETROMASTOID PART.** The petromastoid part of the temporal bone consists of a **mastoid portion** and a **petrous portion**, each of which is best described separately.

**Mastoid Portion.** The **mastoid portion** forms the posterior part of the bone. Its **external surface** (Fig. 4-93) is rough and gives attachment to the occipital belly of the occipitofrontalis muscle, as well as to the auricularis posterior muscle. It is perforated by numerous foramina. One of these, the **mastoid foramen**, is larger, and is often situated near the posterior border. It transmits a vein to the sigmoid sinus (Fig. 4-94) and a small branch of the occipital artery to the dura mater. The position and size of this foramen are variable. It may be absent or situated in the occipital bone, or even in the suture between the temporal and the occipital bones. Inferiorly, the mastoid portion is con-

Fig. 4-97. Left temporal bone. Inferior aspect.

tinued as a conical projection, the **mastoid process**. Although its size and form may vary, this process serves for the insertion of the sternocleidomastoid, splenius capitis, and longissimus capitis muscles. On the medial side of the process is a deep groove, the **mastoid notch**, which gives attachment to the posterior belly of the digastric muscle. Medial to the notch is a shallow furrow, the **occipital groove**, which lodges the occipital artery.

The **internal surface** (Fig. 4-94) of the mastoid portion presents a deep, curved groove, the **sigmoid sulcus**, which lodges the sigmoid sinus. Behind the sulcus is frequently seen the opening of the mastoid foramen. The groove for the sigmoid sinus is separated from the innermost of the mastoid air cells by a very thin lamina of bone, and even this may be partly deficient.

The **superior border** of the mastoid portion is broad and serrated, for articulation with the mastoid angle of the parietal bone. The **posterior border**, also serrated, articulates with the inferior border of the occipital bone between the lateral angle and jugular process. As observable from an external view (Fig. 4-93), the mastoid portion is fused above and anteriorly with the descending process of the squama. Below and posteriorly it enters into the formation of the posterior wall of the tympanic cavity, and extends nearly to the external acoustic meatus.

A section of the mastoid process (Fig. 4-95) shows it to be hollowed out into a number of spaces, the **mastoid cells**. These exhibit a great variability, both in size and number. In the superior part of the mastoid process they are large and irregular, and contain air. Toward the inferior part they diminish in size,

while those at the apex of the process are frequently quite small and contain marrow. Occasionally the mastoid cells are entirely absent, and the process is then solid throughout. Additionally, a large irregular cavity called the **mastoid antrum** is situated at the superior and anterior part of the process (Fig. 4-95). It can be distinguished from the mastoid cells, although it communicates with them. The tympanic antrum also contains air, and it is lined by a prolongation of the mucous membrane of the tympanic cavity with which it communicates as well. The mastoid antrum is bounded above by a thin plate of bone, the **tegmen tympani**, which separates it from the middle fossa of the cranial cavity. Lateral to the antrum is the temporal squama, while medially is the **lateral semicircular canal** of the internal ear which projects into its cavity. It opens anteriorly into that portion of the tympanic cavity known as the **attic** or **epitympanic recess**. The mastoid antrum is a cavity of some considerable size at birth. The mastoid air cells may be regarded as diverticula from the antrum, and begin to appear at or before birth. By the fifth year they are well marked, but their development is not completed until puberty.

**Petrous Portion.** The petrous portion or **pyramid** is wedged between the sphenoid and occipital bones at the base of the skull (see Fig. 4-70). Enclosed within it is the labyrinth containing its receptors for the senses of hearing and equilibration. It presents for examination a base, an apex, three surfaces, and two margins.

**Base and Apex.** The **base** is fused with the internal surfaces of the squamous and mastoid portions.

The **apex**, rough and uneven, is received into the angular interval between the posterior border of the great wing of the sphenoid and the basilar part of the occipital bone. It presents the anterior or internal orifice of the carotid canal and forms the posterolateral boundary of the foramen lacerum.

**Surfaces.** The **anterior surface** helps to form the base of the skull at the posterior part of the middle cranial fossa. It is continuous with the internal or cerebral surface of the squamous portion, to which it is united by the petrosquamous suture, the remains of which are distinct even late in life. It is marked by depressions for the convolutions of the brain, and presents six points for ex-

amination: (1) near the center is the **arcuate eminence** (Fig. 4-94), which indicates the site of the anterior semicircular canal; (2) a shallow depression is found slightly lateral and anterior to the eminence, and indicates the position of the tympanic cavity (Fig. 4-95) and its thin, bony roof, the **tegmen tympani**; (3) a shallow groove, sometimes double, leads into the **hiatus** of the **facial canal** (Fig. 4-95), for the passage of the greater petrosal nerve and the petrosal branch of the middle meningeal artery; (4) lateral to the hiatus is occasionally seen a smaller opening for the passage of the lesser petrosal nerve; (5) near the apex of the bone is found the termination of the **carotid canal** (Fig. 4-95), the wall of which at this site is deficient; and (6) just behind the apex and above the carotid canal is the shallow **trigeminal impression** for the trigeminal (semilunar) ganglion (Fig. 4-70).

The **posterior surface** of the petrous portion forms the anterior part of the posterior cranial fossa (Fig. 4-70). Near the center is the large orifice of the **internal acoustic meatus** (Fig. 4-94) leading into the **internal acoustic canal**. The margins of the meatus are smooth and rounded, and the canal measures about 1 cm in length. It transmits the facial and vestibulocochlear nerves as well as the nervus intermedius, and the internal auditory branch of the basilar artery. Posterior to the internal acoustic meatus is a small slit, almost hidden by a thin plate of bone, that leads to a canal, the **aqueduct of the vestibule**, which transmits the endolymphatic duct together with a small artery and vein. Above and between these two openings is an irregular depression which lodges a process of the dura mater and transmits a small vein. In the infant this depression is represented by a large fossa, the **subarcuate fossa**, which extends backward as a blind tunnel under the anterior semicircular canal.

The **facial canal** is a bony passage within the petrous portion of the temporal bone through which the facial nerve passes. The canal commences at the internal acoustic meatus and ends at the stylomastoid foramen. In its course the canal is initially directed *laterally* toward the medial wall of the tympanic cavity with the cochlea lying in front and the semicircular canals behind. Then the canal suddenly courses *posteriorly* (Fig. 4-96), lying above the **fenestra vestibuli** and the **promontory**. With the semicircular canals still lying above and behind, the fa-

cial canal then arches *downward* toward its exit at the stylomastoid foramen.

The **inferior surface** of the petrous portion of the temporal bone (Fig. 4-97) is rough and irregular, and forms part of the external surface of the base of the skull. It presents a number of features which may be examined: (1) near the apex is a rough quadrilateral surface, partly for the attachment of the levator veli palatini and the cartilaginous portion of the auditory tube, and partly for connection with the basilar part of the occipital bone through the intervention of some dense fibrous tissue; (2) posterior to this is the large circular aperture of the **carotid canal**, which transmits the internal carotid artery and the carotid plexus of sympathetic nerve fibers into the cranium; (3) medial and posterior to the carotid opening and anterior to the jugular fossa is a triangular depression at the apex of which is a small opening, the **cochlear canaliculus**; it lodges a tubular prolongation of the dura mater establishing a communication between the perilymphatic space and the subarachnoid space and it transmits a vein from the cochlea to the internal jugular; (4) posterior to these openings is a deep depression of varying depth and size, the **jugular fossa**, containing the bulb of the internal jugular vein; (5) in the bony ridge between the carotid canal and the jugular fossa is the small **canaliculus for the tympanic nerve** through which passes the tympanic branch of the glossopharyngeal nerve; (6) in the lateral part of the jugular fossa is the **mastoid canaliculus** for the entrance into the petrous portion of the temporal bone of the auricular branch of the vagus nerve; (7) behind the jugular fossa is a quadrilateral area, the **jugular surface**, which is covered with cartilage in the intact body, and which articulates with the jugular process of the occipital bone; (8) extending posteriorly from the carotid canal is the **vaginal process**, a sheath-like plate of bone, which divides behind into two laminae: the lateral lamina is continuous with the tympanic part of the bone; the medial, with the lateral margin of the jugular surface; (9) between these laminae is a sharp spine, the **styloid process**; (10) between the styloid and mastoid processes is the **stylomastoid foramen**, which is the termination of the facial canal and transmits the facial nerve and stylomastoid artery; (11) situated between the tympanic

portion of the temporal bone and the mastoid process is the **tympanomastoid fissure**, through which the auricular branch of the vagus nerve usually exits from the temporal bone.

**Margins.** The **superior margin** of the petrous portion is grooved for the superior petrosal sinus (Fig. 4-94), and gives attachment to the tentorium cerebelli. At its medial extremity is a notch, in which the roots of the trigeminal nerve lie.

The **posterior margin** is marked on its medial half by a sulcus which forms, with a corresponding sulcus on the occipital bone, the channel for the inferior petrosal sinus. The lateral half of the posterior margin presents an excavation, the jugular fossa, which, with the jugular notch on the occipital bone, forms the **jugular foramen**. An eminence occasionally projects from the center of the fossa, dividing the foramen into two.

The petrosquamous suture (Fig. 4-94), which is quite distinct in early life, unites the petrous and squamosal parts. This border of the petrous bone might be considered the **anterior margin**, and here are located two canals, one above the other, separated by a thin plate of bone, the **septum canalis musculotubarii** (Fig. 4-95). Both canals lead into the tympanic cavity. The upper one (**semicanalis m. tensoris tympani**) transmits the tensor tympani muscle; the lower one (**semicanalis tubae auditivae**) forms the bony part of the auditory tube.

The tympanic cavity, auditory ossicles, and internal ear are described with the organ of hearing in the chapter on the Organs of the Senses.

**TYMPANIC PART.** The **tympanic part** of the temporal bone is a curved osseous plate lying inferior to the squama and anterior to the mastoid process (Fig. 4-93). Internally, the tympanic part is fused with the petrous portion, and appears in the angle between it and the squama, where it lies inferior and lateral to the orifice of the auditory tube. Posteriorly, it blends with the squama and mastoid portion and forms the anterior boundary of the tympanomastoid fissure. The **posterior surface** of the tympanic part is concave, and forms the anterior wall, the floor, and part of the posterior wall of the bony **external acoustic meatus**. Medially, this surface presents a narrow furrow, the **tympanic sulcus**, for the attachment of the

tympenic membrane. The **anterior surface** of the tympanic part is quadrilateral and slightly concave. It constitutes the posterior boundary of the mandibular fossa and frequently is in contact with the retromandibular part of the parotid gland. Its **lateral border** is largely free and rough, but does give attachment to the cartilaginous part of the external acoustic meatus. Its **superior border** fuses laterally with the postglenoid process, while medially it bounds the tympanosquamosal fissure. The medial part of the **inferior border** is thin and sharp, while more laterally this border splits to enclose the root of the **styloid process**. It is called the **vaginal process** or **sheath of the styloid process**. The central portion of the tympanic part is thin, and in a considerable percentage of skulls presents a small foramen (of Huschke) which represents a nonossified site.

The **external acoustic meatus** is nearly 2 cm long and is directed inward and slightly forward. At the same time it forms a slight curve, so that the floor of the canal is convex superiorly. Its anterior wall, floor, and inferior part of the posterior wall are formed by the tympanic portion, while the roof and superior part of the posterior wall are formed by the squama. The inner end of the meatus is closed in the intact body by the *tympanic membrane*, thereby separating the tympanic cavity of the middle ear from the external ear. The superior limit of its outer orifice is bounded above by the posterior root of the zygomatic process, immediately below which is sometimes seen the small **suprameatal spine**, situated at the upper and posterior part of the orifice.

The **styloid process** of the temporal bone (Figs. 4-93; 4-97) is slender and pointed, and varies in length from 1 to as much as 4 cm. It projects downward and forward, from the inferior surface of the temporal bone immediately in front of the stylomastoid foramen. Its proximal or **basal part** (*tympanohyal*) is ensheathed by the vaginal process of the tympanic portion, while its distal or **projecting part** (*stylohyal*) gives attachment to the stylohyoid and stylomandibular ligaments, and to the styloglossus, stylohyoid, and stylopharyngeus muscles. The stylohyoid ligament, which may be more or less ossified, extends from the apex of the process to the lesser horn of the hyoid bone. The stylomandibular ligament, which is fibrous in struc-

ture, courses from its attachment on the styloid process below the origin of the styloglossus to the angle of the mandible.

**OSSIFICATION.** The temporal bone is ossified from at least eight centers, exclusive of those for the ossicles of the middle ear and the labyrinthine structures of the internal ear. The centers include one for the squama and zygomatic process, one for the tympanic part, four for the petrous and mastoid parts, and two for the styloid process.

At birth (Fig. 4-98) the temporal bone consists of three principal parts: (1) The **squama** is ossified in membrane from a single nucleus, which appears near the *root of the zygomatic process* about the second month. (2) The **petromastoid part** is developed from at least four centers, which make their appearance in the cartilaginous **otic (ear) capsule** at the end of the fifth month and during the sixth prenatal month. The centers are named according to their position relative to the embryonic otic capsule. One (pro-otic) appears in the *region of the arcuate eminence* and spreads anterior and superior to the internal acoustic meatus, extending to the apex of the bone. It forms part of the cochlea, vestibule, superior semicircular canal, and medial wall of the tympanic cavity. A second (opisthotic) appears at the *promontory on the medial wall of the tympanic cavity* and surrounds the cochlear window. It forms the floor of the tympanic cavity and vestibule, surrounds the carotid canal, invests the lateral and lower part of the cochlea, and spreads medially below the internal acoustic meatus. A third (pterotic) appears *over the lateral semicircular canal* and spreads to the tegmen tympani, roofing in the tympanic cavity and antrum. The fourth (epiotic) appears *near the posterior semicircular canal* and extends to form the mastoid process. (3) At birth the **tympanic part** is an incomplete ring, in the concavity of which is a groove, the tympanic sulcus, for the attachment of the circumference of the tympanic membrane. This ring ossifies in membrane from a single center which appears during the ninth or tenth fetal week.

The **styloid process** is developed from the proximal part of the cartilage of the second visceral or hyoid arch. It ossifies by means of two centers: one for the proximal part, the *tympanohyal*, appears before birth; the other, comprising the rest of the process, is named the *stylohyal*, and does not appear until the second year after birth.

The tympanic ring unites with the squama shortly before birth. The petromastoid part and squama join during the first year, and at about the same time, the tympanohyal portion of the styloid process unites with the inferior surface of the temporal bone (Figs. 4-99; 4-100). The stylohyal portion of the styloid process does not unite with the rest of the bone until after puberty, and in some skulls never at all.

After birth the principal changes in the temporal bone apart from increase in size are: (1) The tym-

**FIG. 4-98.** The three principal parts of the temporal bone at birth. A, Outer surface of petromastoid part. B, Inner surface of tympanic ring. C, Inner surface of squama.

panic ring extends laterally and backward to form the tympanic part of the bone. This growth does not take place at an equal rate all around the circumference of the ring, but occurs most rapidly on its anterior and posterior portions. These outgrowths meet and blend, and thus, for a time, there exists in the floor of the meatus an opening called the *foramen of Huschke*. This foramen is usually closed about the fifth year, but may persist throughout life. (2) The mandibular fossa is at first extremely shallow, and faces laterally as well as inferiorly. It becomes deeper and is ultimately directed inferiorly. Its change in direction is the result of growth phenomena. The part of the squama that forms the fossa lies at first inferior to the level of the zygomatic process. As the base of the skull increases in width, however, this lower part of the squama is directed horizontally inward to contribute to the bony middle fossa of the

skull, and its surfaces therefore come to face superiorly and inferiorly. The attached portion of the zygomatic process also becomes everted and projects like a shelf at right angles to the squama. (3) The mastoid portion is at first quite flat, and the stylomastoid foramen and rudimentary styloid process lie immediately behind the tympanic ring. With the development of the air cells the lateral part of the mastoid portion grows inferiorly and anteriorly to form the mastoid process. The styloid process and stylomastoid foramen now come to lie on the inferior surface. The descent of the foramen is necessarily accompanied by a corresponding lengthening of the facial canal. (4) The downward and forward growth of the mastoid process also pushes forward the tympanic part, so that the portion of it that formed the original floor of the meatus at birth (and contained the foramen of Huschke) is ultimately found in the

**FIG. 4-99.** Lateral aspect of the temporal bone at birth. Note the shallow, laterally oriented mandibular fossa.

**FIG. 4-100.** Medial aspect of the temporal bone at birth. Note the widely open subarcuate fossa.

anterior wall. (5) On the posterior aspect of the petrous portion, the **subarcuate fossa**, which is quite pronounced and widely open at birth (Fig. 4-100), gradually becomes filled and almost obliterated.

**ARTICULATIONS.** The temporal articulates with five bones: occipital, parietal, sphenoid, mandible, and zygomatic.

### SPHENOID BONE

The **sphenoid bone** (*os sphenoidale*; Figs. 4-101 to 4-103) is situated at the base of the skull anterior to the temporal bones and basilar part of the occipital. Its shape somewhat resembles a bat with its wings extended.

The sphenoid bone consists of a median portion or **body**, two **great wings**, two **small wings** extending outward from the sides of the body, and two **pterygoid processes**, which project from the inferior surface of the bone.

**THE BODY.** The **body** (*corpus sphenoidale*), more or less cubical in shape, is hollow and forms two large cavities, the **sphenoidal air sinuses**, which are separated from each other by a thin septum.

The **superior** or **intracranial surface** of the body (Fig. 4-101) presents the prominent **ethmoidal spine** rostrally, for articulation with the cribriform plate of the ethmoid bone. Posterior to this is a smooth surface called the **jugum sphenoidale**, which is slightly

raised in the midline and grooved on each side for the olfactory tracts of the brain. This surface is bounded posteriorly by a ridge that forms the anterior border of the narrow, transversely oriented **chiasmatic groove** (*optic groove*), on which the optic chiasma lies. On each side the groove leads to the **optic canal**, which transmits the optic nerve and ophthalmic artery into the orbital cavity. Posterior to the chiasmatic groove is an elevation, the **tuberculum sellae**. Still more posteriorly is located a hollow depression, the **sella turcica**, the deepest part of which lodges the hypophysis cerebri and is known as the **hypophysial fossa**. The anterior boundary of the sella turcica is completed by two small eminences, one on each side, called the **middle clinoid processes**. The posterior boundary is formed by a square plate of bone, the **dorsum sellae**, which ends at its superior angles in two tubercles, the **posterior clinoid processes**. These may vary considerably in size and form in different skulls. The posterior clinoid processes deepen the sella turcica and give attachment to the tentorium cerebelli. On either side of the dorsum sellae is a notch along which passes the abducent nerve. Inferior to the notch is located the **petrosal process**, which articulates with the apex of the petrous portion of the temporal bone and forms the medial boundary of the foramen lacerum.

FIG. 4-101. The sphenoid bone. Superior aspect.

FIG. 4-102. Sphenoid bone. Posterior aspect, viewed from above.

Posterior to the dorsum sellae is a shallow depression, the **clivus**, which slopes posteriorly and is continuous with a similar groove on the basilar portion of the occipital bone. It supports the pons and the basilar artery.

The **lateral surfaces** of the body are united with the great wings and the medial pterygoid plates. Above the attachment of each

great wing is a broad groove, curved something like the italic letter *f*, named the **carotid sulcus**. It lodges the internal carotid artery, the cavernous sinus, and their related autonomic nerve fibers. Along the posterior part of the lateral margin of this groove, in the angle between the body and the great wing, is a ridge of bone called the **lingula**.

FIG. 4-103. The sphenoid bone. Anterior and inferior surfaces.

The **posterior surface** (Fig. 4-102) is quadrilateral in shape and joined, during infancy and adolescence, to the basilar part of the occipital bone by a disc of hyaline cartilage forming the sphenoccipital synchondrosis. This becomes ossified between the eighteenth and twenty-fifth years.

The **anterior surface** of the body (Fig. 4-103) forms the posterior wall of the nasal cavity and presents, in the midline, the **sphenoidal crest**, which articulates with the perpendicular plate of the ethmoid bone to form part of the septum of the nose. On each side of the crest is a rounded opening leading into the corresponding **sphenoidal air sinus**. These sinuses are two large irregular cavities within the body of the sphenoid bone. They are seldom symmetrical and vary considerably in form and size. Often they are partially subdivided by irregular bony laminae, and occasionally extend into the basilar part of the occipital bone almost as far as the foramen magnum. Partially closed in front by two thin, curved plates of bone, the **sphenoidal conchae**, the sinuses communicate anteriorly through rounded openings with the sphenothmoidal recess of the nasal cavity. The lateral margin of the anterior surface is serrated and articulates with the orbital lamina of the ethmoid bone, completing the posterior ethmoidal cells. The inferior margin articulates with the orbital process of the palatine bone, and the superior margin with the orbital plate of the frontal bone.

The **inferior surface** of the body of the sphenoid bone also forms part of the posterior wall of the nasal cavity. It presents, in the midline, a triangular spine, the **sphenoidal rostrum**, which is continuous with the sphenoidal crest of the anterior surface and is received into a deep fissure between the alae of the vomer. On each side of the rostrum is a projecting lamina, the **vaginal process**, directed medially from the base of the medial pterygoid plate.

**GREAT WINGS.** The **great wings** of the sphenoid bone are two strong processes that arise from the sides of the body and curve upward and laterally. The posterior part of each wing projects as a triangular process, which fits into the angle between the squama and the petrous portion of the temporal bone and presents at its apex an inferiorly directed process, the **sphenoidal spine** (Fig. 4-101).

The **superior or cerebral surface** of each great wing (Figs. 4-70; 4-101) forms part of the middle cranial fossa. It is deeply concave and presents depressions for the convolutions of the temporal lobe of the brain. At its anterior and medial part is a circular aperture, the **foramen rotundum**, through which passes the maxillary nerve. Posterior and lateral to this is the **foramen ovale**, for the transmission of the mandibular nerve, the accessory meningeal artery, and sometimes the lesser petrosal nerve. The lesser petrosal nerve sometimes passes through a special canal (**canaliculus innominatus**) situated medial to the foramen spinosum. Medial to the foramen ovale, a small aperture, the **emissary sphenoidal foramen** (of Vesalius), is frequently seen. It opens inferiorly near the scaphoid fossa, and transmits a small vein from the cavernous sinus to the pterygoid plexus. In the posterior angle near the sphenoidal spine is the **foramen spinosum**, which transmits the middle meningeal vessels and a recurrent branch from the mandibular nerve.

The **temporal surface** (*lateral surface*; Fig. 4-62) is convex, and divided by a transverse ridge, the **infratemporal crest**, into **temporal** and **infratemporal portions**. The superior or temporal portion gives attachment to the temporalis muscle, while the inferior or infratemporal, smaller in size, enters into the formation of the **infratemporal fossa** and, together with the infratemporal crest, affords attachment to the pterygoideus lateralis muscle. It is pierced by the **foramen ovale** and **foramen spinosum**, and at its posterior part is the **sphenoidal spine**, which frequently is grooved on its medial surface for the chorda tympani nerve. To the sphenoidal spine are attached the sphenomandibular ligament and the tensor veli palatini muscle. Medial to the anterior extremity of the infratemporal crest is a triangular process that serves to increase the attachment of the lateral pterygoid muscle. A ridge extends downward and medialward from this process on the anterior part of the lateral pterygoid plate. This ridge defines the anterior limit of the infratemporal surface and, in the articulated skull, the posterior boundary of the **pterygomaxillary fissure**.

The **orbital surface** of the great wing is smooth and quadrilateral (Fig. 4-103) and forms the posterior part of the lateral wall of the orbit. Its serrated superior margin articu-

lates with the orbital plate of the frontal bone. Its rounded *inferior margin* forms the posterolateral boundary of the **inferior orbital fissure**. Its sharp *medial margin* forms the inferior boundary of the **superior orbital fissure** (Fig. 4-102). Projecting from about its center is a little tubercle that gives attachment to part of the fibrous tendinous ring from which arise the rectus muscles of the eyeball. At this site on the ring arises the inferior head of the rectus lateralis oculi muscle. At the upper part of this medial margin is a notch for the transmission of a recurrent branch of the lacrimal artery. Its *lateral margin* is serrated and articulates with the zygomatic bone. Inferior to the medial end of the superior orbital fissure is a grooved surface, which forms the posterior wall of the **pterygopalatine fossa** and is pierced by the **foramen rotundum**.

The **posterior margin of the great wing** (Figs. 4-101; 4-102), which extends from the body to the sphenoidal spine, is irregular in shape. Medially near the body it forms the anterior wall of the **foramen lacerum**. It also presents the posterior aperture of the **pterygoid canal** (Fig. 4-102), through which passes the corresponding nerve and artery. Its lateral half articulates, by means of a cartilaginous joint, with the petrous portion of the temporal bone, forming the **sphenopetrosal synchondrosis**. Between the two bones, on the inferior surface of the skull, is a furrow, the **sulcus tubae auditivae**, which lodges the cartilaginous part of the auditory tube. Anterior to the sphenoidal spine, the concave, serrated **squamous margin**, bevelled at the expense of the inner table inferiorly, and of the outer table superiorly, articulates with the temporal squama. At the tip of the great wing is a triangular portion, the **parietal margin** (Fig. 4-102), bevelled at the expense of the internal surface, for articulation with the sphenoidal angle of the parietal bone. On the lateral surface of the skull, this site is named the **pterion**. Medial to this is a triangular, serrated surface, the **frontal margin** for articulation with the frontal bone (Fig. 4-103). This surface is continuous medially with the sharp edge, which forms the inferior boundary of the superior orbital fissure, and laterally with the **zygomatic margin** for articulation with the zygomatic bone (Fig. 4-103).

**LESSER WINGS.** The lesser wings of the sphenoid bone are two thin triangular plates, which arise from the superior and anterior

parts of the sphenoidal body and, projecting laterally, end in sharp points (Fig. 4-101).

The **superior surface** is flat and supports part of the frontal lobe of the brain. The **inferior surface** forms the posterior part of the roof of the orbit and the superior boundary of the **superior orbital fissure**. The **anterior border** is serrated for articulation with the orbital plate of the frontal bone. The **posterior border**, smooth and rounded, is received into the lateral fissure of the brain; the medial end of this border forms the **anterior clinoid process** and gives attachment to the tentorium cerebelli. The anterior clinoid process is sometimes united to the middle clinoid process by a spicule of bone, and when this happens the termination of the groove for the internal carotid artery is converted into the **caroticoclinoid foramen**. The small wing is connected to the body by two roots: a thin, flat superior root and a thicker, triangular inferior root. Between the two roots is the **optic canal** for the transmission of the optic nerve and ophthalmic artery.

A **superior orbital fissure** (Fig. 4-103) is triangular in shape and leads from the cavity of the cranium into that of the orbit. It is bounded *medially* by the sphenoidal body, *superiorly* by the small wing, *inferiorly* by the medial margin of the orbital surface of the great wing, and completed *laterally* by the frontal bone between the great and lesser wings. Into the orbit, the fissure transmits the oculomotor, trochlear, and abducent nerves, the three branches of the ophthalmic division of the trigeminal nerve, some sympathetic nerve filaments from the internal carotid and cavernous plexuses, and the orbital branch of the middle meningeal artery. Into the cranial cavity from the orbit, the fissure transmits a recurrent branch from the lacrimal artery to the dura mater and the ophthalmic veins.

**PTERYGOID PROCESSES.** The **pterygoid processes**, one on each side of the sphenoid bone, project downward perpendicularly from the inferior region where the body and great wing unite. Each pterygoid process consists of a **medial** and **lateral pterygoid plate**, the superior parts of which are fused anteriorly. The **pterygopalatine groove**, a vertical sulcus, descends anterior to the line of fusion. The plates are separated inferiorly by an angular cleft, the **pterygoid fissure**, the rough margins of which articulate with the pyramidal process of the palatine bone. The two plates diverge posteriorly and enclose

between them a V-shaped fossa, the **pterygoid fossa** (Fig. 4-102), which contains the medial pterygoid and tensor veli palatini muscles. Superior to this fossa is a small, oval depression, the **scaphoid fossa**, which gives origin to part of the tensor veli palatini. The anterior surface of the pterygoid process is broad and triangular near its root, where it forms the posterior wall of the pterygopalatine fossa. The anterior orifice of the pterygoid canal opens at this site (Fig. 4-103).

The **lateral pterygoid plate** is broad, thin, and everted. Its *lateral* surface forms part of the medial wall of the infratemporal fossa and gives origin to the lateral pterygoid muscle. Its *medial* surface forms part of the pterygoid fossa and gives attachment to the medial pterygoid.

The **medial pterygoid plate** is narrower and longer than the lateral. It curves laterally at its inferior extremity into a hook-like process, the **pterygoid hamulus**, around which the tendon of the tensor veli palatini muscle glides. The *lateral* surface of this plate forms part of the pterygoid fossa, and the belly of the tensor veli palatini lies adjacent to it. The *medial* surface of the medial pterygoid plate constitutes the lateral boundary of the choana or posterior aperture of the corresponding nasal cavity. Superiorly the medial plate is prolonged onto the inferior surface of the body as a thin lamina, named the **vaginal process** (Fig. 4-103), which articulates anteriorly with the sphenoidal process of the palatine and posteriorly with the ala of the vomer. The angular prominence between the posterior margin of the vaginal process and the medial border of the scaphoid fossa is named the **pterygoid tubercle**, and immediately superior to this is the posterior opening of the **pterygoid canal** (Fig. 4-102). On the inferior surface of the vaginal process is a furrow, which is converted into the **palatovaginal canal** by the sphenoidal process of the palatine bone. This canal transmits the pharyngeal branch of the maxillary artery and the pharyngeal nerve from the pterygopalatine ganglion. The pharyngobasilar fascia is attached to the entire length of the posterior margin of the medial pterygoid plate, and the constrictor pharyngis superior muscle takes origin from its inferior third. Projecting dorsally from near the middle of the posterior edge of this plate is an angular process, the **processus tubarius**, which supports the pharyngeal end of the auditory tube. The anterior margin of

the medial pterygoid plate articulates with the posterior border of the perpendicular plate of the palatine bone.

The **pterygoid canal** (*Vidian canal*) courses anteroposteriorly within the part of the body of the sphenoid to which each pterygoid process is attached. When the sphenoidal sinus is extensive, the canal is covered by a ridge of bone in the floor of the sinus. The posterior orifice opens into the foramen lacerum (Fig. 4-102), the anterior into the pterygopalatine fossa (Fig. 4-103). The canal measures 1 to 2 mm in diameter and transmits the nerve of the pterygoid canal (*Vidian nerve*) and a small branch of the pterygopalatine portion of the maxillary artery called the artery of the pterygoid canal.

The **sphenoidal conchae** (Fig. 4-103) are two thin, curved plates, situated at the anterior part of the body of the sphenoid. An aperture of variable size exists in the anterior wall of each, and through this the **sphenoidal sinus** opens into the sphenoethmoidal recess of the nasal cavity. The inferior surface of these plates is convex and forms part of the roof of the nasal cavity.

**OSSIFICATION.** The greater part of the sphenoid bone is first formed in cartilage. Until the seventh or eighth month of fetal life the body of the sphenoid may be considered to consist of two parts. One part, anterior to the tuberculum sellae, is named the **presphenoid** and is continuous with the lesser wings. The other, comprising the sella turcica and dorsum sellae, is called the **postsphenoid** and has attached to it the great wings and pterygoid processes. There are fourteen ossification centers in all, six for the presphenoid and eight for the postsphenoid.

**Presphenoid Ossification.** About the ninth week of fetal life an ossific center appears for each of the lesser wings (orbitosphenoids) just lateral to the optic canal. Shortly afterward two nuclei appear in the presphenoid part of the body. The sphenoidal conchae are each developed from ossification centers, which make their appearance about the fifth prenatal month. At birth the conchae consist of small triangular laminae, and it is not until the third year that they become hollow and cone-shaped. About the fourth year the conchae join the labyrinths of the ethmoid, and between the ninth and twelfth years their union with the sphenoid becomes ossified.

**Postsphenoid Ossification.** The first ossific nuclei are those for the great wings (ali-sphenoids). One makes its appearance at the base of each wing between the foramen rotundum and foramen ovale

about the eighth week. These centers ossify only the more proximal parts of the great wings, while the orbital plate and the lateral part of the great wings, as well as the lateral pterygoid plates, are ossified in membrane. Two centers for the postsphenoid part of the body appear soon after those of the great wings. These develop on each side of the sella turcica and fuse about the middle of fetal life. Each medial pterygoid plate (with the exception of its hamulus) is ossified in membrane, and its center probably appears about the ninth or tenth week. The hamulus becomes chondrified during the third month, and almost at once undergoes ossification. The medial and lateral pterygoid plates join about the sixth month. During the fourth month a center appears for each lingula and speedily joins the rest of the bone.

The presphenoid fuses to the postsphenoid portion of the body about the eighth month, and at birth the bone consists of three parts (Fig. 4-104): a central, which includes the body and small wings, and two lateral, each consisting of a great wing and pterygoid process. In the first year after birth the great wings and body unite in the region of the pterygoid canal. The lesser wings extend inward above the anterior part of the body and, meeting in the midline, form an elevated smooth surface, termed the *jugum sphenoidale*. By the twenty-fifth year the sphenoid and occipital bones are completely fused.

The *craniopharyngeal canal*, through which the hypophyseal diverticulum is connected with buccal ectoderm in fetal life, occasionally persists between the presphenoid and postsphenoid parts of the sphenoid bone. Epithelial lined cysts (craniopharyngeomas) may develop along the course of a persisting craniopharyngeal canal.

The *sphenoid sinuses* are present as minute cavities in the body of the sphenoid at the time of birth, but do not attain their full size until after puberty.

**INTRINSIC LIGAMENTS.** The more important of these are: the **pterygospinous**, stretching between the sphenoidal spine and the superior part of the lateral pterygoid plate; the **interclinoid**, a fibrous process joining the anterior to the posterior clinoid process; and the **caroticoclinoid**, connecting the anterior to the middle clinoid process. These ligaments occasionally ossify.

**ARTICULATIONS.** Centrally positioned, the sphenoid bone articulates with all the other bones of the cerebral cranium. Totally, it articulates with twelve bones: four single—the vomer, ethmoid, frontal, and occipital; and four paired—the parietal, temporal, zygomatic, and palatine. It also sometimes articulates with the tuberosity of the maxilla.

### ETHMOID BONE

The **ethmoid bone** (*os ethmoidale*; Figs. 4-105 to 4-108) is cuboidal in shape and exceedingly light and spongy. It is situated at the anterior part of the base of the cranium, between the two orbits, and forms part of the medial wall of each orbit as well as part of the nasal septum and much of the roof and lateral walls of the nasal cavity. The ethmoid consists of four parts: a horizontal or **cribriform plate**, forming part of the base of the cranium; a **perpendicular plate**, constituting part of the nasal septum; and two lateral masses called **ethmoidal labyrinths**.

The **cribriform plate** (Fig. 4-105) is received into the ethmoidal notch of the frontal bone and forms most of the roof of the nasal cavities. Projecting superiorly into the cranial fossa from the midline of this plate is a thick, smooth triangular process, the **crista galli**, so called from its resemblance to a cock's comb. The long thin posterior border of the crista galli serves for the attachment of the falx cerebri. The anterior border of the cribriform plate is short and thick, and it presents two small projecting **alae**, which are received into corresponding depressions in the frontal bone, thereby completing the **foramen cecum**. Its sides are smooth and sometimes bulge due to the presence of a small air sinus in the interior. On each side of the crista galli, the cribriform plate is nar-

FIG. 4-104. Sphenoid bone at birth. Posterior aspect.

FIG. 4-105. Ethmoid bone from above.

row and deeply grooved; it supports the olfactory bulb and is perforated by the **olfactory foramina** for the passage of the olfactory nerves. At the anterior part of the cribriform plate, on each side of the crista galli, is a small fissure that is occupied by a process of dura mater. Lateral to this fissure is a notch or foramen, which transmits the nasociliary nerve; from this notch a groove extends backward to the anterior ethmoid foramen.

The **perpendicular plate** (Figs. 4-106; 4-107) is a thin, flattened lamina, which descends from the cribriform plate and assists in forming the septum of the nose. The ante-

rior border articulates with the spine of the frontal bone and the crest of the nasal bones. The **posterior border** articulates with the sphenoidal crest above and the vomer below. The **inferior border** is thicker than the posterior, and serves for the attachment of the septal cartilage of the nose. The surfaces of the plate are smooth except superiorly, where numerous grooves and canals lead from the medial foramina in the cribriform plate and lodge filaments of the olfactory nerves.

The **labyrinth** or **lateral mass** (Fig. 4-107) consists of a number of thin-walled cellular cavities which are arranged in three groups, the **anterior, middle, and posterior ethmoidal air cells**. These are interposed between two vertical plates of bone. The lateral plate forms part of the orbit; the medial, part of the corresponding nasal cavity. In the disarticulated bone many of the cells appear open, but in the articulated skull they are completely closed except where their ostia open into the nasal cavity.

The **superior surface of the labyrinth** (Fig. 4-105) presents a number of incompletely closed cells, the walls of which are completed, in the articulated skull, by the edges of the ethmoidal notch of the frontal bone. Crossing this surface on each side are two grooves, which are converted into canals by articulation with the frontal bone. These are the **anterior and posterior ethmoidal canals**, which open on the inner wall of the orbit. The **posterior surface of the labyrinth** (Fig.

FIG. 4-106. Perpendicular plate of ethmoid bone, exposed by removing the right labyrinth. Lines of articulation are shown along the borders.

FIG. 4-107. Ethmoid bone. Posterior aspect.

4-107) presents large irregular cellular cavities, which are closed by articulation with the sphenoidal conchae and orbital processes of the palatine bones. The **lateral surface of the labyrinth** (Fig. 4-108) is formed by a thin, smooth, oblong plate, the **lamina orbitalis**, which covers the middle and posterior ethmoidal cells and forms a large part of the medial wall of the orbit. This plate articulates *above* with the orbital plate of the frontal bone, *below* with the maxilla and orbital process of the palatine, *anteriorly* with the lacrimal, and *posteriorly* with the sphenoid.

Anterior to the lamina orbitalis are some air cells, which are overlapped and completed by the lacrimal bone and the frontal process of the maxilla. A thin, curved, bony lamina, the **uncinate process**, projects inferiorly and posteriorly from this part of the labyrinth (Figs. 4-107; 4-108). It forms part of the medial wall of the maxillary sinus and articulates with the ethmoidal process of the inferior nasal concha.

The medial surface of the labyrinth (Fig.

4-109) forms part of the lateral wall of the corresponding nasal cavity. It consists of a thin, rough lamella, which extends downward from the cribriform plate and ends below in a free, scroll-shaped, convoluted margin, the **middle nasal concha**. Superiorly, the medial surface is marked by numerous grooves lodging branches of the olfactory nerves which are distributed to the uppermost nasal mucous membrane. The posterior part of the medial surface of the labyrinth is subdivided by a narrow antero-posterior fissure, the **superior meatus** of the nose, which separates the **superior nasal concha** from the middle concha. The middle concha extends along the whole anteroposterior extent of the medial surface of the labyrinth, and its margin is free and thick. The superior concha extends only about half as far anteriorly as the middle concha, and its free margin is less thick. Posteriorly, the superior meatus extends upward as a deep groove under cover of the superior concha, and the **posterior ethmoidal air cells** open into it. The **middle meatus** of the nose is an extensive narrow channel extending anteroposteriorly and upward under cover of the middle concha. Continuing upward and forward from the middle meatus is a deep curved passage, the **infundibulum**. The **anterior ethmoidal cells** open into the infundibulum, and in about half the skulls the infundibulum continues upward as the **frontonasal duct** into the **frontal sinus**. The **ostium** of the **maxillary sinus** opens into the bottom of the middle part of the infundibulum. The lateral wall of the middle meatus contains a rounded swelling called the **bullae ethmoidalis**. The **middle ethmoid air cells** lie within the bullae and open above it. The portion of the wall of the meatus posterior to

FIG. 4-108. Ethmoid bone from the right lateral aspect.

**Fig. 4-109.** Lateral wall of the right nasal cavity, showing the ethmoid bone (red) and the inferior nasal concha (blue).

the infundibulum is lacking in bone and may fail to be closed by mucous membrane in the intact body, thus providing an **accessory opening** into the **maxillary sinus**.

**OSSIFICATION.** The ethmoid is ossified in the cartilage of the nasal capsule by three centers: one for the perpendicular plate and one for each labyrinth.

The labyrinths are developed first as granules of bone that make their appearance between the fourth and fifth months of fetal life in the region of the lamina orbitalis, which then extends into the conchae. At birth, the ethmoid bone consists of two partially ossified labyrinths, which are small and poorly developed. The remainder of the bone is still cartilaginous. During the first postnatal year the perpendicular plate and crista galli begin to ossify from a single center, fusing with the labyrinths at about the beginning of the second year. The cribriform plate is ossified partly from the perpendicular plate and partly from the labyrinths. The ethmoidal cells commence forming before birth, and become well defined by the third year. They form by bone resorption, even as the ethmoid bone grows, and come to occupy the two labyrinths.

**ARTICULATIONS.** The ethmoid bone articulates with thirteen other bones. Two of these, the frontal and sphenoid, are of the cranium. The remaining

eleven are of the face, and include the two nasals, two maxillae, two lacrimals, two palatines, two inferior nasal conchae, and the vomer.

### SUTURAL BONES

In addition to the usual centers of ossification of the cranium, other centers may occur in the course of the sutures, especially those related to the parietal bones. These may give rise to irregular, isolated bones, termed **sutural** or **Wormian bones**. They occur most frequently in the course of the lambdoid suture, but are occasionally seen at the fontanelles, especially the posterior. A **pterion ossicle**, or **epipteric bone**, sometimes exists between the sphenoidal angle of the parietal bone and the great wing of the sphenoid. Sutural bones have a tendency to be more or less symmetrical on the two sides of the skull, and vary much in size. Their number is generally limited to two or three, but more than a hundred have been found in the skull of an adult hydrocephalic subject. Sutural bones are rarely seen in lines of union between facial bones.

### NASAL BONES

The **nasal bones** (Figs. 4-110 to 4-112) are two small oblong bones which vary in form and size in different individuals. They are placed side by side between the frontal processes of the maxillary bones, and by their junction, form the bridge of the nose (Fig. 4-64). The nasal bones are wider and thinner inferiorly, where they join the nasal cartilages, than they are superiorly. Each nasal bone presents two surfaces and four borders.

The **internal surface** (Fig. 4-110) is concave from side to side and is traversed by a longitudinal groove, the **ethmoidal sulcus**, for the passage of the external nasal branch of the anterior ethmoidal nerve. The **external surface** (Fig. 4-111) is convex from side to side and is perforated at about its center by one or two foramina for the transmission of small external nasal veins. It is covered by the procerus and nasalis muscles.

The **superior border** is narrow, thick, and serrated for articulation with the nasal notch of the frontal bone. The **inferior border** is thin and gives attachment to the lateral cartilage of the nose. Near its middle is a small notch which marks the end of the ethmoidal sulcus lodging the external nasal nerve. The **lateral border** is serrated and articulates with the frontal process of the maxilla. The **medial border** is thicker above than below and articulates with the opposite nasal bone. This border is prolonged posteriorly as a vertical crest which forms a small part of the nasal septum. This crest articulates with the nasal spine of the frontal bone, the perpendicular plate of the ethmoid, and the cartilage of the nasal septum.

**FIG. 4-110.** Right nasal bone. Internal surface. Borders of articulation indicated in green.

**FIG. 4-111.** Right nasal bone. External surface. Borders of articulation indicated in green.

**OSSIFICATION.** Each nasal bone is ossified from one center which appears during the eighth or ninth week of fetal life in the membrane overlying the anterior part of the cartilaginous nasal capsule. The nasal bones at birth are nearly square in shape, but as facial development ensues, they become nearly three times as long as they are wide.

**ARTICULATIONS.** Each nasal bone articulates with four bones: two of the cranium—the frontal and ethmoid, and two of the face—the opposite nasal and the maxilla.

### MAXILLARY BONE

The **maxillae** (upper jaw) are the largest bones of the face, excepting the mandible, and by their union form the whole of the upper jaw. Each assists in forming the boundaries of four cavities: the roof of the mouth, the floor and lateral wall of the nasal cavity, the floor of the orbit, and the maxillary sinus. The maxillae support the upper teeth and enter into the formation of two fossae, the infratemporal and pterygopalatine, and two fissures, the inferior orbital and pterygomaxillary. Each bone consists of a **body** and four processes—zygomatic, frontal, alveolar, and palatine.

**BODY OF THE MAXILLA.** The **body** is somewhat pyramidal in shape and is hollowed by a large cavity, the **maxillary sinus**. It has four surfaces—an anterior or facial, a posterior or infratemporal, a superior or orbital, and a medial or nasal.

The **anterior or facial surface** (Fig. 4-112) is directed forward and laterally, and presents inferiorly a series of eminences corresponding to the positions of the roots of the teeth. Superior to those of the incisor teeth is a depression, the **incisive fossa** (Fig. 4-113), which gives origin to the depressor septi muscle. To the alveolar border below the

FIG. 4-112. Lateral aspect of the maxilla showing the articulations of the nasal and lacrimal bones with the maxilla.

fossa a slip of the orbicularis oris is attached, and above and a little lateral to it, the nasalis muscle arises. Lateral to the incisive fossa is another depression, the **canine fossa**. It is larger and deeper than the incisive fossa, and is separated from it by a vertical ridge, the **canine eminence**, corresponding to the

socket of the canine tooth. The canine fossa gives origin to the levator anguli oris. Above the canine fossa is the **infraorbital foramen**, which is the anterior orifice of the infraorbital canal and transmits the infraorbital vessels and nerve. Above the foramen is the sharp, inferior margin of the orbit, which

FIG. 4-113. Left maxilla. Outer surface.

affords attachment to the levator labii superioris muscle. Medially, the anterior surface is limited by a deep concavity, the **nasal notch**, which ends below in a pointed process. This latter process joins with the one from the opposite maxilla to form the **anterior nasal spine**.

The **posterior or infratemporal surface** (Fig. 4-113) is convex, directed laterally and posteriorly, and forms the anterior wall of the infratemporal fossa. It is separated from the anterior surface of the maxilla by the zygomatic process and by a strong ridge, extending upward from the socket of the first molar tooth. It is pierced about its center by the apertures of two or three **alveolar canals** which transmit the posterior superior alveolar vessels and nerves. At the inferior part of this surface is a rounded eminence, the **maxillary tuberosity**, especially prominent after the growth of the wisdom tooth. The tuberosity is rough on its medial side for articulation with the pyramidal process of the palatine bone. It gives origin to a few fibers of the medial pterygoid muscle, and in some instances it articulates with the lateral pterygoid plate of the sphenoid. Immediately above this is a smooth surface, which forms the anterior boundary of the pterygopalatine fossa and presents a laterally directed groove for the maxillary nerve. This groove is continuous with the infraorbital groove on the orbital surface.

The **superior or orbital surface** (Figs. 4-65; 4-113) is smooth and triangular and forms the greater part of the floor of the orbit. It is bounded medially by an irregular margin, the **lacrimal notch**, behind which it articulates with the lacrimal bone, the lamina orbitalis of the ethmoid bone, and the orbital process of the palatine bone. It is bounded posteriorly by a smooth rounded edge, which forms the anterior margin of the inferior orbital fissure. At times it articulates at its lateral extremity with the orbital surface of the great wing of the sphenoid. **Anteriorly**, the orbital surface is limited by a small portion of the circumference of the orbit, continuous medially with the frontal process and laterally with the zygomatic process. Near the middle of the posterior part of the orbital surface is the **infraorbital groove**, for the passage of the infraorbital vessels and nerve. The groove begins near the middle of the posterior border (Fig. 4-112), where it is continuous with the groove for the maxillary

nerve. Passing rostrally, the infraorbital groove ends in a canal which then subdivides into two canals. One of these, the **infraorbital canal**, opens just below the margin of the orbit at the infraorbital foramen. The other canal, which is smaller, courses downward in the substance of the anterior wall of the maxillary sinus, and transmits the anterior superior alveolar vessels and nerve to the front teeth. From the posterior part of the infraorbital canal, an additional small canal sometimes courses in the lateral wall of the sinus, conveying the middle alveolar nerve to the premolar teeth. Anteromedially on the orbital surface, just lateral to the lacrimal groove, is a depression from which arises the inferior oblique muscle of the eyeball.

The **nasal surface** (Fig. 4-114) assists in the formation of the lateral wall of the corresponding nasal cavity and presents posterosuperiorly a large, irregular opening leading into the **maxillary sinus**. At the superior border of this aperture (also called the **maxillary hiatus**) are some incomplete air cells which, in the articulated skull, are closed in by the ethmoid and lacrimal bones. Below the aperture of the maxillary sinus is a smooth concavity which forms part of the inferior meatus of the nasal cavity, and posterior to it is a rough surface for articulation with the perpendicular part of the palatine bone. A groove commencing near the middle of the posterior border and running obliquely downward and forward is converted into the **greater palatine canal** by articulation with the palatine bone. Rostral to the opening of the sinus is the **lacrimal groove**, which is converted into the **nasolacrimal canal** by the lacrimal bone and inferior nasal concha. This canal opens into the inferior meatus of the nose and transmits the nasolacrimal duct. More anteriorly the bone is marked by an oblique ridge, the **conchal crest**, for articulation with the inferior nasal concha. The shallow concavity superior to this ridge forms part of the atrium of the middle meatus, and that inferior to it, part of the inferior meatus.

**MAXILLARY SINUS.** The **maxillary sinus** (Figs. 4-114; 4-115) is a large pyramidal cavity within the body of the maxilla. Its walls are thin and correspond to the nasal, orbital, anterior, and infratemporal surfaces of the body of the bone. Its **apex** is oriented laterally and corresponds to the zygomatic process. The **base** of the maxillary sinus is

FIG. 4-114. Left maxilla. Nasal surface.

FIG. 4-115. The infratemporal surface of the maxilla has been opened from the lateral side to reveal the maxillary sinus. This exposure also demonstrates the nasal (medial) wall of the sinus and the three bony structures that partially cover it: perpendicular plate of the palatine bone, the inferior nasal concha, and the uncinate process of the ethmoid bone.

bounded by the nasal wall, which is directed medially and presents, in the disarticulated bone, a large, irregular aperture, communicating with the nasal cavity. In the articulated skull this aperture is partly closed by the following bones: the uncinat process of the ethmoid, the maxillary process of the inferior nasal concha, the perpendicular plate of the palatine, and a small part of the lacrimal (Figs. 4-72; 4-73; 4-114; 4-115). In the dried skull the sinus communicates with the middle meatus, generally by two small apertures between the above-mentioned bones. In the intact body, however, usually one small opening exists near the upper part of the cavity, since the other is closed by mucous membrane. On the posterior wall of the maxillary sinus are ridges formed by the **alveolar canals**, which transmit the posterior superior alveolar vessels and nerves to the molar teeth.

The floor of the sinus is formed by the alveolar process of the maxilla. When the sinus is average in size, its floor is on a level with the floor of the nose; if the sinus is large, it extends below this level. Projecting into the floor of the sinus are several conical processes corresponding to the roots of the teeth. The bone separating the roots of the teeth from the sinus is quite thin. The roots of the upper molar teeth occasionally extend into the sinus, but diseased roots of any of the maxillary teeth can communicate with the sinus. The infraorbital canal usually projects into the cavity as a well-marked ridge extending from the roof to the anterior wall. The size of the sinus cavity varies in different skulls, and even on the two sides of the same skull.

**PROCESSES OF THE MAXILLA.** Of the four bony processes of the maxilla, two—the **zygomatic** and **frontal**—belong to the upper part of the bone, and two—the **alveolar** and **palatine**—belong to the lower part.

The **zygomatic process** (Fig. 4-112) is a rough triangular eminence, situated at the angle of separation of the anterior, infratemporal, and orbital surfaces. Above it is rough and serrated for articulation with the zygomatic bone. Below it presents a prominent arched border which marks the division between the anterior and infratemporal surfaces. In front it forms part of the anterior surface of the maxilla, while behind it is concave and forms part of the infratemporal fossa.

The **frontal process** (Figs. 4-112; 4-113) is a strong plate which projects upward and backward and forms part of the lateral boundary of the nose. Its *lateral surface* is smooth and gives attachment to the levator labii superioris alaeque nasi, the orbicularis oculi, and the medial palpebral ligament. Its *medial surface* forms a portion of the lateral wall of the nasal cavity. At its upper part is a rough, uneven area which articulates with the ethmoid bone and closes the anterior ethmoidal cells. Inferior to this is an oblique ridge, the **ethmoidal crest**, the posterior end of which articulates with the middle nasal concha and forms the upper limit of the atrium of the middle meatus, while the anterior part, which is termed the **agger nasi**, is an elevation on the lateral wall of the nasal cavity. The superior border articulates with the frontal bone while the anterior border articulates with the nasal bone. The posterior border is thick and hollowed into a groove, which is continuous below with the lacrimal groove on the nasal surface of the body. The lateral margin of the groove is named the **anterior lacrimal crest**. At its junction with the orbital surface is the small **lacrimal tubercle**, which serves as a guide to the position of the lacrimal sac. The posterior border of the frontal process articulates with the lacrimal bone to form the **lacrimal fossa** for the lodgement of the lacrimal sac.

The **alveolar process** (Figs. 4-113; 4-114) is the thickest and most spongy part of the maxilla. Its arched shape is broader behind than anteriorly, and it is excavated by eight deep cavities for the reception of the teeth. These sockets vary in size and depth according to the teeth they contain. The socket for the canine tooth is the deepest, while those for the molars are widest and subdivided by bony septa into three smaller sockets, each receiving a root. The incisors and the second upper premolar generally have one root and therefore their sockets are single, but the upper first premolar frequently has a bifid root and therefore a two-cavity socket. The buccinator arises from the outer surface of the alveolar process, as far anteriorly as the first molar tooth. When the maxillae are articulated with each other, their alveolar processes together form the **alveolar arch**, and the center of the anterior margin of this arch is named the **alveolar point**.

The **palatine process** (Figs. 4-114; 4-116) is horizontal and projects medially from the

**Fig. 4-116.** The inferior aspect of the bony palate and the alveolar arch. In this young specimen the incisive suture was well delineated. Note that the skeleton of the hard palate consists of the palatine processes of the maxillae and the horizontal laminae (plates) of the palatine bones.

nasal surface of the bone. It is thick and strong and forms a considerable part of the floor of the nose and roof of the mouth. Its inferior surface (Fig. 4-116) is concave, rough, and uneven, and forms, with the palatine process of the opposite bone, the anterior three-fourths of the **hard palate**. It is perforated by numerous foramina for the passage of nutrient vessels and presents little depressions for the palatine glands. At the posterior part of the lateral border near the last molar tooth are grooves for the transmission of the greater palatine vessels and nerve. When the two maxillae are articulated, an oblong depression, the **incisive fossa**, is seen in the midline immediately behind the incisor teeth. In this fossa the orifices of two lateral canals, named the **right and left incisive canals** (or *foramina of Stenson*), are visible. Through each passes a terminal branch of the greater palatine artery into the nasal cavity from the oral cavity

and the nasopalatine nerve into the oral cavity from the nasal cavity. Occasionally two additional canals are present in the midline. They are termed the **anterior and posterior median incisive canals** (or the *foramina of Scarpa*) and, when present, transmit branches of the nasopalatine nerves, the left passing through the anterior and the right through the posterior canal. On the inferior surface of the palatine process, a delicate linear **incisive suture**, best seen in young skulls, may sometimes be noticed extending laterally and rostrally on both sides of the incisive fossa to the interval between the lateral incisor and the canine tooth. The small part anterior to this suture constitutes the **incisive bone** or **premaxilla**, which in most vertebrates is identifiable as an independent bone. It includes the whole thickness of the alveolus, the corresponding part of the floor of the nose, and the anterior nasal spine, and contains the sockets of the incisor teeth.

The classic view that the human incisive bone is quite comparable to the premaxilla of other vertebrates has been questioned on the basis of certain ossification studies.

The superior surface of the palatine process is smooth and concave from side to side and forms a large part of the floor of the nasal cavity (Fig. 4-114). The lateral border of the palatine process is fused with the nasal surface of the body of the maxilla above and the alveolar process below. The medial border is thicker anteriorly than behind, and is raised into a ridge, the **nasal crest**, which, with the corresponding ridge of the opposite maxilla, forms a groove for the reception of the vomer. The anterior part of this ridge is raised considerably and is named the **incisor crest**. This is prolonged forward into a sharp process which, together with the same process from the opposite maxilla, forms the **anterior nasal spine**. The posterior border of the palatine process is serrated for articulation with the horizontal part of the palatine bone.

**OSSIFICATION.** Several descriptions of the ossification in membrane of the maxilla have been offered over the years and there is still some uncertainty on the subject. The commonly read and classically described mode of ossification goes back to, among others, that of Franklin Mall (1906), and was reasserted by Chase (1942). These authors claimed that the maxilla ossifies from only two centers, one for the maxilla proper, which appears above the canine fossa, and one for the premaxilla, which is located in front of the developing incisor teeth. These two centers appear between the sixth and eighth week of fetal life and unite at the beginning of the third month. Others (Kölliker, 1885; Fawcett, 1911; Woo, 1949) described at least two centers of ossification in the premaxilla, one along the incisor tooth germ and the other along the medial wall of the paraseptal cartilage, thereby claiming that the maxillary bone as a whole develops from at least three ossification centers. Finally, some investigators (Wood et al., 1967, 1969) feel that separate maxillary and premaxillary ossification centers do not develop, and that the entire maxilla ossifies from a single primary ossification lamina that extends from the region of the body of the maxilla.

Controversy on the premaxillary bone actually dates to the appearance in 1543 of Vesalius' great work, *De Humani Corporis Fabrica*, in which Vesalius repudiated the views of Galen who had described the human premaxilla as a separate bone, the condition Galen had encountered in his dissections of monkeys, dogs, and swine. Vesalius denied for the first time the existence of the premaxillary suture line on the facial aspect of the human skull, which Galen

had described, even if the palatal suture line could at times be seen. In a very complete review of this subject, Ashley-Montague (1935) stated "that *in primates, with the exception of man*, the premaxilla may be observed upon the facial aspect of the skull suturally quite distinctly separated from the maxilla in almost all sub-adult as well as in many adult individuals. *In late fetal and postnatal man*, no trace of a separation of this bone from the maxilla upon the face is observed, although the palatine portion of the premaxilla may be distinctly observed in the majority of infant crania, and may be encountered in some 26.0 percent of adult crania."

**ARTICULATIONS.** The maxilla articulates with nine bones: *two of the cranium*, the frontal and ethmoid, and *seven of the face*, the nasal, zygomatic, lacrimal, inferior nasal concha, palatine, vomer, and the opposite maxilla. Sometimes it articulates with the orbital surface and sometimes with the lateral pterygoid plate of the sphenoid.

**CHANGES WITH AGE.** *At birth* the transverse and anteroposterior diameters of the bone are each greater than the vertical (Figs. 4-117; 4-118). The frontal process is well marked and the body of the bone consists of little more than the alveolar process with the teeth sockets reaching almost to the floor of the orbit. The maxillary sinus is represented by a furrow on the lateral wall of the nasal cavity. *In the adult* the vertical diameter is the greatest, owing to the development of the alveolar process and the increase in size of the sinus. *In old age* the maxilla reverts in some measure to the infantile condition. Its height is diminished, and after loss of the teeth the alveolar process is absorbed, and the lower part of the bone is contracted and reduced in thickness.

#### PALATINE BONE

The **palatine bone** is situated in the posterior part of each nasal cavity between the maxilla and the pterygoid process of the sphenoid (Fig. 4-119). Each palatine bone assists in forming the posterior part of the hard palate, part of the floor and lateral wall of the nasal cavity, and the floor of the orbit. It enters into the formation of the **pterygo-palatine**, **pterygoid**, and **infratemporal fos-**

Fig. 4-117. Anterior surface of maxilla at birth.

FIG. 4-118. Inferior surface of maxilla at birth.

sae, and the inferior orbital fissure. The palatine bone somewhat resembles the letter L, and consists of a **horizontal** and a **perpendicular plate**. It also presents three prominent processes, the **pyramidal**, which is directed backward and laterally from the junction of the two parts, and the **orbital** and **sphenoidal processes**, which extend from the vertical part and are separated by the **sphenopalatine notch**.

**HORIZONTAL PLATE.** The horizontal plate resembles somewhat the palatine process of the maxilla, and it is quadrilateral in shape, presenting two surfaces and four borders (Figs. 4-120; 4-121).

The **nasal** or **superior surface** is smooth and concave from side to side, and forms the posterior part of the floor of the nasal cavity. The **palatine** or **inferior surface** is more rough and forms, with the corresponding surface of the opposite bone, the posterior

one-fourth of the **hard palate** (Fig. 4-116). Near its posterior margin may be seen a transverse ridge, called the **palatine crest**, to which attaches a part of the aponeurosis of the tensor veli palatini muscle.

The **anterior border** is serrated, and articulates with the palatine process of the maxilla. The **posterior border** is concave, free, and serves for the attachment of the palatine aponeurosis, which forms the tendinous core of the soft palate. Its medial end is sharp and pointed and, when united with that of the opposite bone, forms a projecting process, the **posterior nasal spine** for the attachment of the musculus uvulae. The **lateral border** is united to the lower margin of the perpendicular plate and is grooved by the lower end of the greater palatine canal. The **medial border** is the thickest and is serrated for articulation with the corresponding border of the opposite palatine bone. Its superior edge is raised into a ridge, which, united with the opposing ridge, forms the **nasal crest** for articulation with the posterior part of the lower edge of the vomer.

**PERPENDICULAR PLATE.** The perpendicular plate is thin and long, and presents two surfaces and four borders (Figs. 4-120; 4-121).

The inferior part of the **medial** or **nasal surface** exhibits a broad, shallow depression, which forms part of the inferior meatus of the nasal cavity. Superior to this is a prominent horizontal ridge, the **conchal**

FIG. 4-119. Articulation of left palatine bone with maxilla. Viewed from the medial aspect.

FIG. 4-120. Left palatine bone. Nasal aspect. Enlarged.

crest, which articulates with the inferior nasal concha. Still higher is a second broad, shallow depression, which forms part of the middle meatus and is limited by the **ethmoidal crest**, for articulation with the middle nasal concha. Above the ethmoidal crest is a narrower and deeper horizontal groove, which forms part of the superior meatus.

The **lateral** or **maxillary surface** is rough and irregular throughout the greater part of its extent for articulation with the nasal surface of the maxilla. Its posterosuperior part is smooth where it helps form the medial wall of the pterygopalatine fossa. Its anterior portion is also smooth, and here it forms the posterior part of the medial wall of the maxillary sinus. On the posterior part of the maxillary surface is the deep, vertical **greater palatine groove**, which upon articulation with the maxilla becomes the greater palatine canal. Through the canal courses the greater palatine vessels and nerve.

The **anterior border** is thin and irregular. Opposite the conchal crest is a pointed, projecting lamina, the **maxillary process**, which articulates with the inferior nasal concha and helps form the medial wall of the maxillary sinus (Fig. 4-115). The **posterior border** presents a deep groove, the edges of which are serrated for articulation with the medial pterygoid plate of the sphenoid. This border is continuous above with the sphenoidal process and expands into the **pyramidal process**. The **superior border** is marked by

FIG. 4-121. Left palatine bone. Posterior aspect. Enlarged.

the **orbital process** in front and the **sphenoidal process** behind. These processes are separated by the **sphenopalatine notch**, which is converted into the **sphenopalatine foramen** by articulation with the inferior surface of the body of the sphenoid. In the articulated skull this foramen leads from the pterygopalatine fossa into the posterior part of the nasal cavity and transmits the sphenopalatine vessels and the posterior superior nasal nerves. The **inferior border** is fused with the lateral edge of the horizontal plate. Immediately anterior to the pyramidal process is the lower end of the greater palatine groove.

**PYRAMIDAL PROCESS.** The **pyramidal process** (Fig. 4-121) projects laterally from the junction of the horizontal and perpendicular plates and is received into the angular interval between the inferior extremities of the pterygoid plates. On its **posterior surface** is a smooth, grooved triangular area limited on each side by a rough articular furrow. The furrows articulate with the pterygoid plates, while the grooved intermediate area completes the lower part of the pterygoid fossa and gives origin to a few fibers of the medial pterygoid muscle. The anterior part of the **lateral surface** is rough, for articulation with the tuberosity of the maxilla. Its posterior part consists of a smooth triangular area which appears, in the articulated skull, between the tuberosity of the maxilla and the inferior part of the lateral pterygoid plate, and completes the infratemporal fossa. On

the **base** of the pyramidal process, close to its union with the horizontal plate, are the **lesser palatine foramina** for the transmission of the lesser palatine nerves and vessels.

**ORBITAL PROCESS.** The **orbital process** (Figs. 4-119 to 4-121) is directed superiorly and laterally from the perpendicular plate, to which it is connected by a constricted neck. It encloses an air sinus and presents five surfaces, three of which are articular and two nonarticular. The articular surfaces are: (1) the **anterior** or **maxillary**, oblong in form, and rough for articulation with the maxilla; (2) the **posterior** or **sphenoidal**, directed backward, upward, and medially and presenting the opening of the air sinus that usually communicates with the sphenoidal sinus (the margins of the opening are serrated for articulation with the sphenoidal concha); (3) the **medial** or **ethmoidal**, directed forward and articulating with the labyrinth of the ethmoid. In some cases the air sinus opens on this surface of the bone and then communicates with the posterior ethmoidal cells. More rarely it opens on both the ethmoidal and sphenoidal surfaces, and then communicates with the posterior ethmoidal cells and the sphenoidal sinus. The nonarticular surfaces are: (1) the **superior** or **orbital**, which is triangular in shape, is directed upward and laterally, and forms the posterior part of the floor of the orbit; and (2) the **lateral**, which is oblong in form and separated from the orbital surface by a rounded border that enters into the formation of the inferior orbital fissure.

**SPHENOIDAL PROCESS.** The **sphenoidal process** (Fig. 4-119) is a thin, compressed plate, much smaller than the orbital, and directed superiorly and medially. It presents three surfaces and three borders. The **superior surface** articulates with the root of the medial pterygoid plate and the inferior surface of the sphenoidal concha. It presents a groove that contributes to the formation of the palatovaginal canal. The **medial surface** is concave and forms a small part of the lateral wall of the nasal cavity. The **lateral surface** is divided into an articular portion, which is rough, for articulation with the medial pterygoid plate, and a nonarticular portion, which is smooth and forms part of the pterygopalatine fossa. The **medial border** reaches as far as the ala of the vomer for articulation. The **anterior border** forms the posterior boundary of the sphenopalatine

notch. The serrated **posterior border** articulates with the vaginal process of the medial pterygoid plate.

The **orbital** and **sphenoidal processes** are separated from one another by the **sphenopalatine notch** (Fig. 4-119), which becomes the sphenopalatine foramen by the inferior surface of the sphenoid bone. Sometimes the two processes are united above and form between them a complete sphenopalatine foramen (Fig. 4-120), or the notch may be crossed by one or more spicules of bone, giving rise to two or more foramina.

**OSSIFICATION.** The palatine bone is ossified in membrane from a single center, which makes its appearance about the eighth week of fetal life at the angle of junction between the horizontal and perpendicular plates of the bone. From this point ossification spreads medialward to the horizontal plate and downward into the pyramidal process. By the tenth week ossification has spread upward into the perpendicular plate and its orbital and sphenoidal processes. At the time of birth the height of the perpendicular plate is about equal to the transverse width of the horizontal plate. As the maxilla grows and the nasal cavities increase in depth, the perpendicular plate in the adult eventually measures about twice as much as the horizontal plate.

**ARTICULATIONS.** The palatine bone articulates with six other bones: the sphenoid, ethmoid, maxilla, inferior nasal concha, vomer, and the opposite palatine.

#### INFERIOR NASAL CONCHA

The **inferior nasal conchae** are a slender pair of bones, each of which extends horizontally along the lateral wall of the nasal cavity (Figs. 4-72; 4-73; 4-109). Each inferior concha consists of a lamina of spongy bone, curled upon itself like a scroll, and it is so located as to separate the middle meatus in the nasal cavity from the inferior meatus. It has two surfaces, two borders, and two extremities.

The **medial surface** (Fig. 4-122) is convex, perforated by numerous apertures, and traversed by longitudinal grooves for the lodgment of vessels. The **lateral surface** is concave (Fig. 4-123), faces the lateral wall of the nasal cavity, and forms part of the inferior meatus. Its **superior border** is thin and irregular, and articulates with four bones: the maxillary, lacrimal, ethmoid, and palatine bones. This border may be divided into three portions: anterior, middle, and posterior. The **anterior** articulates with the

FIG. 4-122. Right inferior nasal concha. Medial surface.

conchal crest of the maxilla; the posterior with the conchal crest of the palatine. The middle portion presents three well-marked processes, which vary much in size and form. Of these, the **lacrimal process** is small and pointed and is situated at the junction of the anterior one-fourth with the posterior three-fourths of the bone. By its apex, it articulates with the descending process of the lacrimal bone, and by its margins, with the nasolacrimal groove on the medial surface of the maxilla just behind the frontal process. Thus, it assists in forming the canal for the nasolacrimal duct. Posterior to the lacrimal process is a broad, thin plate, the **ethmoidal process**, which ascends to articulate with the uncinate process of the ethmoid. Extending inferiorly and laterally from the ethmoidal process is a thin lamina, the **maxillary process**, which articulates with the maxilla and forms a part of the medial wall of the maxillary sinus. The **inferior border** is free, thick, and spongy in structure, more especially in the middle of the bone. Both **extremities** are more or less pointed, the posterior being the more tapering.

**OSSIFICATION.** The inferior nasal concha is ossified from a single center, which appears about the fifth month of fetal life in the lateral wall of the cartilaginous nasal capsule.

**ARTICULATIONS.** The inferior nasal concha articulates with four bones. From anterior to posterior these are the maxillary, lacrimal, ethmoid, and palatine (Fig. 4-122).

FIG. 4-123. Right inferior nasal concha. Lateral surface.

## THE VOMER

The **vomer** is situated in the median plane, but its anterior portion is frequently deviated to one side or the other. It is thin, unpaired, flat, and irregularly quadrilateral, and forms the posterior and inferior part of the **nasal septum** (Fig. 4-124). It has two surfaces and four borders. The **surfaces** are marked by small furrows for blood vessels, and on each is the **nasopalatine groove**, which courses obliquely downward and forward and lodges the nasopalatine nerve and vessels (Fig. 4-125). The **superior border**, the thickest, presents a deep furrow, bounded on each side by a horizontal projecting **ala** of bone. The furrow receives the rostrum of the sphenoid, while the margins of the alae articulate with the vaginal processes of the medial pterygoid plates of the sphenoid behind, and with the sphenoidal processes of the palatine bones in front. The **inferior border** articulates with the nasal crest formed by the maxillae and palatine bones. The **anterior border** is the longest, and it slopes downward and forward. Its superior half is fused with the perpendicular plate of the ethmoid, while its inferior half is grooved to receive the inferior margin of the septal cartilage of the nose. The **posterior border** is free and concave, and separates the choanae, or posterior nasal apertures. It is thick and bifid above, and thin below.

**OSSIFICATION.** At an early period the septum of the nose consists of a cartilaginous plate. The posterior superior part of this cartilage is ossified to form the perpendicular plate of the ethmoid. Its anterior inferior portion persists as the septal cartilage, while the vomer is ossified in the connective tissue membrane covering its posterior inferior part. Two ossification centers, one on each side of the midline, appear about the eighth week of fetal life in this part of the membrane, and hence the vomer consists primarily of two lamellae. At about the third month these unite below the cartilaginous plate, and thus a deep groove is formed in which the septal cartilage of the nose becomes lodged. As growth proceeds, the union of the ossified lamellae extends anteriorly and superiorly, and at the same time the intervening plate of cartilage undergoes absorption. By puberty the lamellae are almost completely united to form a median plate, but evidence of the bilaminar origin of the bone is seen in the everted alae of its upper border and the groove on its anterior margin.

**ARTICULATIONS.** The vomer articulates with six bones: two of the cranium—the sphenoid and ethmoid; and four of the face—the two maxillae and the two palatine bones. It also articulates with the septal cartilage of the nose.

**FIG. 4-124.** The anterior portion of the skull has been bisected in the midline leaving the bony nasal septum which separates the two nasal cavities. Observe that the septum is a thin sheet of bone formed almost entirely by the vomer and the perpendicular plate of the ethmoid, although small contributions to the septum are made by the rostrum of the sphenoid posteriorly and the nasal spine of the frontal bone anteriorly. Note the articular surfaces of the vomer with the sphenoid, ethmoid, maxillae, and palatine bones. Additionally, it articulates with the septal cartilage.

### LACRIMAL BONE

The **lacrimal bone**, the smallest and most fragile bone of the face, is situated at the anterior part of the medial wall of the orbit (Fig. 4-112). It is quadrilateral in shape and presents two surfaces and four borders.

The **lateral or orbital surface** (Fig. 4-126) is divided by a vertical ridge, the **posterior lacrimal crest**, into two parts. Anterior to the crest is a longitudinal groove, the **lacrimal**

**sulcus**, which unites with the frontal process of the maxilla to form the **fossa of the lacrimal sac**. The upper part of this fossa lodges the lacrimal sac, and the lower part, the nasolacrimal duct. Posterior to the crest, the lateral surface of the lacrimal bone is smooth and forms part of the medial wall of the orbit. The crest, with a part of the orbital surface immediately behind it, gives origin to the lacrimal part of the orbicularis oculi muscle. The posterior lacrimal crest ends

**FIG. 4-125.** The vomer. Left lateral aspect.

**FIG. 4-126.** The left lacrimal bone. The lateral (or orbital) aspect.

inferiorly in a small, hook-like projection, the **lacrimal hamulus**, which articulates with the lacrimal tubercle of the maxilla, and completes the upper orifice of the osseous canal for the nasolacrimal duct. The lacrimal hamulus sometimes exists as a separate small bone, and it is then called the **lesser lacrimal bone**.

The **medial or nasal surface** presents a longitudinal furrow, corresponding to the crest on the lateral surface. The area anterior and inferior to this furrow forms part of the middle meatus of the nose. The portion posterior and superior to the furrow articulates with the ethmoid and completes some of the anterior ethmoidal cells.

The **anterior border** articulates with the frontal process of the maxilla, while the **posterior border** articulates with the lamina orbitalis of the ethmoid. The **superior border** articulates with the frontal bone, and the **inferior border** is divided by the lower edge of the posterior lacrimal crest into a posterior part, which articulates with the orbital plate of the maxilla, and an **anterior part**, which is prolonged downward as a descending process. The latter articulates with the lacrimal process of the inferior nasal concha and assists in forming the canal for the nasolacrimal duct.

**OSSIFICATION.** The lacrimal bone is ossified from a single center, which appears about the twelfth week of prenatal life in the membrane covering the cartilaginous nasal capsule. Ossification of the hamulus from a separate center has been reported.

**ARTICULATIONS.** The lacrimal bone articulates with four bones: two of the cranium—the frontal and ethmoid, and two of the facial skeleton—the maxilla and the inferior nasal concha.

## ZYGOMATIC BONE

The **zygomatic bone** (Figs. 4-127 to 4-129) is nearly quadrangular and is situated in the upper lateral aspect of the face. It forms the prominence of the cheek, part of the lateral wall and floor of the orbit, and part of the bony walls of the temporal and infratemporal fossae. It presents lateral, orbital, and temporal surfaces; frontal and temporal processes; and five borders.

The **lateral surface** (Figs. 4-127; 4-128) is convex, and it is perforated toward the orbital border by a small aperture, the **zygomaticofacial foramen**, through which passes

Fig. 4-127. Left zygomatic bone in situ.

the zygomaticofacial nerve and vessels. Below this foramen is a slight elevation, which gives origin to the zygomaticus minor and the levator labii superioris muscles.

The **temporal surface** (Fig. 4-129) is directed medially and posteriorly. It is concave and presents medially a rough, triangular area for articulation with the maxilla. Laterally, its smooth, concave surface extends superiorly behind the frontal process to form the bony anterior boundary of the temporal fossa. More posteriorly the temporal surface of the zygomatic bone also forms

Fig. 4-128. Left zygomatic bone. Lateral surface.

**Fig. 4-129.** Left zygomatic bone, temporal surface. Note that the posteromedial border articulates with two bones, the sphenoid and the maxilla.

part of the boundary of the infratemporal fossa. Near the center of this surface is the **zygomaticotemporal foramen** for the transmission of the zygomaticotemporal nerve.

The **orbital surface** forms, by its junction with the orbital surface of the maxilla and with the great wing of the sphenoid, part of the floor and lateral wall of the orbit. Usually it presents the orifices of two canals, the **zygomatico-orbital foramina**, which communicate with the zygomaticotemporal and zygomaticofacial foramina.

The **frontal process** (Fig. 4-128) is thick and serrated, and articulates superiorly with the zygomatic process of the frontal bone and posteriorly with the great wing of the sphenoid and the orbital surface of the maxilla (Fig. 4-129). On its orbital surface, just within the orbital margin and about 1 cm below the zygomaticofrontal suture is the **tuberculum marginale**. Onto this tubercle, located laterally in the orbit, are attached: (1) the lateral cheek ligament, (2) the lateral palpebral ligament, (3) the suspensory ligament of the eye, and (4) a lateral extension of the aponeurosis of the levator palpebral superioris muscle.

The **temporal process** is blunt and its oblique serrated margin helps to form the zygomatic arch by articulation with the zygomatic process of the temporal bone.

In the older nomenclature, reference is also made to the **maxillary process** of the zygomatic bone (Fig. 4-128), but the more recent *Nomina Anatomica* does not recognize this as an officially named structure.

The term simply refers to the rough, triangular inferior extension of the bone, which articulates with the maxilla.

The **orbital border** (anterosuperior) is smooth and rounded (Fig. 4-128) and forms approximately one-third of the bony circumference of the orbit. The **maxillary border** (anteroinferior) is rough and, in apposition with the maxilla, helps to form the prominence of the cheek (Fig. 4-127). Close to the orbit, this border gives origin to the levator labii superioris muscle. The **temporal border** (posterosuperior) extends from the frontozygomatic suture to the temporozygomatic suture (Fig. 4-128). It is curved and smooth and gives attachment to the temporal fascia. The **posteroinferior border** allows attachment of the masseter muscle (Fig. 4-129). On the medial or temporal aspect of the zygomatic bone can be observed the **posteromedial border**, which is serrated and articulates with the great wing of the sphenoid bone above and the maxilla below (Fig. 4-129). Between these two articular surfaces, this border also presents a short, concave, nonarticular part, which forms the lateral boundary for the inferior orbital fissure. Occasionally this nonarticular part is absent, and the fissure is then completed by the junction of the maxilla and sphenoid, or by the interposition of a small sutural bone in the angular interval between them.

**OSSIFICATION.** The zygomatic bone ossifies in membrane from a single center, which appears just beneath and to the lateral aspect of the orbit at about the eighth week of prenatal life. After birth the bone is sometimes divided by a horizontal suture into an upper large and a lower smaller division, and in some animals the zygomatic bone is composed of two parts, consistent with this human variation.

**ARTICULATIONS.** The zygomatic bone articulates with four other bones: the frontal, sphenoidal, temporal, and maxillary.

## Appendicular Skeleton

The bones by which the upper and lower limbs are attached to the trunk constitute respectively the shoulder and pelvic girdles. The **shoulder girdle** or girdle of the superior limbs is formed by the scapulae and clavicles. Ventrally it is completed by the cranial end of the sternum, with which the medial end of both clavicles articulates. Dorsally the skeleton of the shoulder girdle is incomplete

and the scapulae are connected to the trunk by muscles only. The **pelvic girdle** or girdle of the inferior limbs is formed by the hip bones, which articulate with each other at the symphysis pubis. The pelvic girdle is completed posteriorly by the sacrum, thereby forming a complete ring, massive and comparatively rigid, in marked contrast to the light and mobile shoulder girdle.

## BONES OF THE SHOULDER GIRDLE AND UPPER LIMB

### THE CLAVICLE

The **clavicle** (Figs. 4-130; 4-131), commonly called the collar bone, forms the ventral portion of the shoulder girdle. It is a long, curved bone, which lies subcutaneously across the root of the neck. It is directed nearly horizontally toward the tip of the shoulder, immediately above the first rib. It articulates medially with the manubrium sterni and laterally with the acromion of the scapula.

In the female the clavicle is generally shorter, thinner, less curved, and smoother than in the male. In those persons who perform considerable manual labor it becomes thicker and more curved, and its ridges for muscular attachment are prominently marked.

The clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to the arm. Accordingly, it is absent in those animals whose forelimbs are used only for progression, but is present for the most part in animals whose anterior extremities are clawed and used for prehension. In some animals, however, such as many of the carnivora, it is only a rudimentary bone which

is suspended among the muscles, not articulating with either the scapula or the sternum.

The human clavicle presents a double curvature. At the sternal end the convexity is directed ventrally, at the acromial end the convexity is dorsal. It is convenient to describe the lateral one-third of the clavicle and its **acromial extremity** and the medial two-thirds with its **sternal extremity**. Additionally, the clavicle presents two surfaces and two borders.

**LATERAL ONE-THIRD.** The **cranial** or **superior surface** of the lateral third of the clavicle is flat, rough, and marked toward the borders by impressions for the attachment of the trapezius and deltoid muscles (Fig. 4-130). Between these impressions the strip of bone is smooth and subcutaneous. The **caudal** or **inferior surface** at the dorsal border near the flat end presents a rough eminence, the **conoid tubercle** (Fig. 4-131), for the attachment of the conoid ligament. An oblique ridge, the **trapezoid line**, runs ventrally and laterally from this tubercle and affords attachment to the trapezoid ligament. The **dorsal border** of the lateral third is convex, rough, and thicker than the ventral border, and receives the insertion of the trapezius muscle. The **ventral border** is concave, thin, and rough, and gives origin to the deltoid muscle. The distal extremity or acromial end of the lateral one-third of the clavicle articulates with the acromion of the scapula and will be described below.

**MEDIAL TWO-THIRDS.** The medial two-thirds of the clavicle is rounded or prismatic and curved with a ventral convexity. Medially, its **ventral border** presents an elliptical surface for the attachment of the clavicular head of the pectoralis major muscle. The ventral border and free surface of the bone between the attachments of the pectoralis

FIG. 4-130. Left clavicle. Superior surface.

FIG. 4-131. Left clavicle. Inferior surface. Attachment of articular capsules indicated by solid blue lines.

major and deltoid is smooth. The superior surface of the medial two-thirds is smooth and rounded laterally, but becomes more roughened medially for the attachment of the sternocleidomastoid muscle. The ventral aspect of the middle portion of the clavicle is smooth, convex, and nearly subcutaneous, being covered only by skin and platysma muscle fibers. The **dorsal border**, from the conoid tubercle to the costal tuberosity, forms the posterior boundary of the groove for the subclavius muscle, and gives attachment to a layer of cervical fascia which envelops the omohyoid muscle. The surface of the bone along the dorsal border is smooth and is oriented toward the root of the neck. It is concave mediolaterally, and lies in relation to the course of the transverse scapular vessels. This aspect of the clavicle, at the junction of the curves of the bone, is also adjacent to the brachial plexus of nerves and the subclavian vessels. It gives attachment, near the sternal extremity, to part of the sternohyoid muscle, and presents, near the middle, an oblique foramen directed lateralward, which transmits the chief nutrient artery of the bone. On the **inferior surface** of the medial two-thirds of the clavicle, near its sternal extremity, is a broad roughened area, the **costal tuberosity**, which is rather more than 2 cm in length and to which attaches the costoclavicular ligament. The rest of this surface is occupied by a groove, which gives attachment to the subclavius muscle. The clavipectoral fascia, which splits to enclose the subclavius muscle, is attached to the margins of the groove.

**STERNAL EXTREMITY.** The **sternal extremity** of the clavicle is directed medialward and presents an **articular facet**, which articulates with the clavicular notch of the manubrium sterni through the intervention of an

**articular disc.** The inferior part of the articular facet continues as a triangular surface for articulation with the *cartilage of the first rib*. The circumference of the articular surface is roughened for the attachment of numerous ligaments. The sternal end of the clavicle projects above the level of the manubrium sternum and is covered by the sternal end of the sternocleidomastoid muscle. It is easily palpable and frequently can be seen subcutaneously in the root of the neck.

**ACROMIAL EXTREMITY.** The **acromial extremity** presents a small flat oval surface directed obliquely downward for articulation with the *acromion of the scapula*. The circumference of the articular facet is rough, especially above, for the attachment of the acromioclavicular ligaments. The acromial extremity of the clavicle projects somewhat above the acromion of the scapula, and the acromioclavicular joint is palpable about 3 cm medial to the lateral border of the acromion.

**STRUCTURE.** The clavicle consists of cancellous bone enveloped by a compact layer, which is much thicker in the intermediate part than at the extremities of the bone.

**OSSIFICATION.** The clavicle begins to ossify before any other bone in the body. Ossification commences from three centers: *two primary centers*, a medial and a lateral, for the clavicular shaft, which appear during the fifth or sixth week of fetal life, and a *secondary center* for the sternal end, which appears about the eighteenth or twentieth year and unites with the rest of the bone about the twenty-fifth year (Fig. 4-132).

**FRACTURES OF THE CLAVICLE.** The clavicle is fractured more frequently than any other bone in the body. This usually is caused by a fall that results in an inordinate force applied to the bone from the hand or the shoulder. The usual location of the fracture is at the junction of the lateral and intermediate thirds of the bone. The lateral fragment of bone then

**Fig. 4-132.** Diagram showing the three centers of ossification of the clavicle.

becomes displaced downward by contractions of the pectoralis major and teres major muscles, and by the weight of the arm. The medial fragment is tilted upward by contractions of the sternocleidomastoid and trapezius muscles.

### THE SCAPULA

The **scapula** or shoulder blade is a large, flat, triangular bone located on the dorsal aspect of the thorax, extending between the second and seventh ribs. It articulates with the clavicle and humerus laterally to form the shoulder joint and is attached to the vertebral column medially by means of muscles. It has two **surfaces** (costal and dorsal) and is marked by three prominent **bony processes**: the spine of the scapula, the acromion, and the coracoid process. Additionally, it has three **borders** (superior, lateral or axillary, and medial or vertebral), and three **angles** (inferior, superior, and lateral).

**SURFACES.** The **costal surface** (Fig. 4-133) presents a broad concavity, the **subscapular fossa**. The medial two-thirds of the fossa are marked by several oblique ridges which course laterally and superiorly. These ridges give attachment to the tendinous origin and the surfaces between them to the fleshy fibers of the subscapularis muscle. The lateral third of the fossa is smooth and also covered by the fibers of this muscle. The fossa is separated from the two extremities of the medial or vertebral border by smooth triangular areas at both the medial and inferior angles. The interval between these two angles is marked by a narrow ridge, which at times is deficient. The triangular areas at the angles and this intervening ridge receive the insertion of the serratus anterior muscle.

The **dorsal surface** (Fig. 4-134) is arched from above downward and is subdivided into two unequal parts by a prominent plate of bone, the **spine of the scapula**. The smaller portion above the spine is called the **supraspinatous fossa**, and that below it the **infraspinatous fossa**.

The **supraspinatous fossa** is a smooth concavity, which is broader at its vertebral than at its humeral end. Its medial two-thirds give origin to the supraspinatus muscle.

The **infraspinatous fossa** is about three times as large as the supraspinatous fossa. It has a shallow concavity toward the cranial part of its vertebral margin, a prominent convexity at its center, and a deep groove near the axillary border. The medial two-thirds of the fossa give origin to the infraspinatus muscle and the lateral third is covered by this muscle.

The dorsal surface of the scapula is marked near the axillary border by an elevated ridge, which runs from the lower part of the glenoid cavity, downward and backward to the medial or vertebral border, about 2.5 cm above the inferior angle. The ridge serves for the attachment of a fibrous septum which separates the infraspinatus muscle from the teres major and teres minor muscles. The surface between the ridge and the axillary border is narrow in the cranial two-thirds of its extent and is crossed near its center by a groove for the passage of the circumflex scapular vessels. This ridge affords attachment to the teres minor above, while its caudal third presents a broader, somewhat triangular surface, which gives origin to the teres major. The latissimus dorsi muscle glides over this lower region, and frequently a few of its muscle fibers arise at the inferior angle of the scapula. An oblique line from the axillary border to the elevated ridge has attached to it a fibrous septum which separates the teres muscles from each other (Fig. 4-134).

**BONY PROCESSES.** The scapula possesses three important bony processes: the spine of the scapula, the acromion, and the coracoid process.

The **spine of the scapula** (Fig. 4-134) is a strong, triangular bony projection from the dorsal surface of the scapula, and it separates the supraspinatous and infraspinatous fossae. It begins at the medial or vertebral border as a smooth, triangular zone over which the tendon of insertion of the trapezius glides, and gradually becoming more elevated, it ends in the acromion, which overhangs the shoulder joint. The spine is flattened from above downward and the apex of its triangular shape is directed toward the medial border of the scapula. The spine presents two surfaces and three bor-

FIG. 4-134. Left scapula. Dorsal surface.

the medial boundary of the **great scapular notch**, which serves to connect the supraspinatus and infraspinatus fossae.

The **acromion** is a flattened, lateral prolongation of the spine of the scapula, which forms the summit of the shoulder and overhangs the glenoid cavity. Its **superior surface** is convex and rough, and affords attachment to some fibers of the deltoid muscle, while the rest of its extent is subcutaneous. Its **inferior surface** is smooth and concave. Its **lateral border** is thick and irregular, and

presents three or four tubercles for the tendinous origins of the deltoid muscle. Its **medial border**, shorter than the lateral, is concave, gives attachment to a portion of the trapezius, and presents about its center a small, oval **surface for articulation** with the acromial end of the clavicle. Its **apex**, which corresponds to the point of meeting of these two borders, is thin and has attached to it the coracoacromial ligament. Inferiorly, where the lateral border of the acromion becomes continuous with the lower border of the

crest of the spine of the scapula, is located the **acromial angle** (Fig. 4-135), which can be palpated subcutaneously and therefore used as a landmark.

The **coracoid process** (Figs. 4-134; 4-135) is a thick, curved bony projection attached by a broad base to the upper part of the neck of the scapula. From its base it is initially directed upward and medially, then it becomes somewhat thinner and changes direction to project upward and laterally. With the arm by the side, the tip of the coracoid process is oriented anteriorly and can be palpated by applying deep pressure through

the anterior part of the deltoid muscle about 2.5 mm below the lateral part of the clavicle on the lateral side of the infraclavicular fossa. Its concave surface faces laterally and is smooth to accommodate the passage of the tendon of the subscapularis muscle. The distal portion is horizontal, and its convex outer surface is rough and irregular for the attachment of the pectoralis minor muscle. Its medial and lateral borders are rough. The former gives attachment to the pectoralis minor and the latter to the coracoacromial ligament. The **apex** is embraced by the conjoined tendon of origin of the coracobrachialis and short head of the biceps brachii and gives attachment to the clavipectoral fascia. On the medial part of the root of the coracoid process is a rough impression for the attachment of the conoid ligament. Coursing from it obliquely to the convex surface of the horizontal portion is an elevated ridge for the attachment of the trapezoid ligament.

**BORDERS.** The **superior border** of the scapula is the shortest and thinnest of the three scapular borders. It is concave, and extends from the medial angle to the base of the coracoid process (Fig. 4-134). At its lateral part is a semicircular notch, the **scapular notch**, formed partly by the base of the coracoid process. This notch is converted into a foramen by the superior transverse ligament (which is at times ossified), and serves for the passage of the suprascapular nerve. The adjacent part of the superior border affords attachment to the omohyoid muscle.

The **lateral (axillary) border** is the thickest of the three borders. It begins above at the lower margin of the glenoid cavity and inclines obliquely downward and backward to the inferior angle. Immediately below the glenoid cavity is a rough impression, the **infraglenoid tubercle**, about 2.5 cm in length, which gives origin to the long head of the triceps brachii muscle. The inferior third is thin and sharp, and serves for the attachment of a few fibers of the teres major behind and the subscapularis muscle in front (Figs. 4-133; 4-134).

The **medial (vertebral) border** is the longest of the three borders, and extends from the superior to the inferior angle. It is arched and intermediate in thickness between the superior and lateral borders, and the portion of it above the spine forms an obtuse angle

FIG. 4-135. Left scapula. Lateral view.

with the part below. This border presents an anterior and a posterior lip, and an intermediate narrow area. The **anterior lip** affords attachment to the serratus anterior muscle (Fig. 4-133), while the **posterior lip** gives attachment to the supraspinatus muscle above the spine and the infraspinatus muscle below (Fig. 4-134). To the area between the two lips is inserted the levator scapulae muscle above the triangular surface at the commencement of the spine. The rhomboid minor muscle inserts on the edge of that surface and rhomboid major below it (Fig. 4-134). The latter is attached by means of a fibrous arch, connected above to the lower part of the triangular surface at the base of the spine and below to the lower part of the border.

**ANGLES.** The **superior angle** (Fig. 4-134), formed by the junction of the superior and medial (or vertebral) borders, is thin, smooth, and rounded, and gives attachment to a few fibers of the levator scapulae muscle. The **inferior angle** (Figs. 4-134; 4-135) is formed by the union of the medial (vertebral) and lateral (axillary) borders. It is thick and rough, and its dorsal surface affords attachment to the teres major and frequently to a few fibers of the latissimus dorsi. The **lateral angle** (Fig. 4-134) is the thickest part of the bone, and the adjacent broadened process is sometimes called the **head of the scapula**. This is connected with the rest of the bone by a slightly constricted **neck**. It is this region of the scapula that enters into the formation of the shoulder joint, and it is hollowed out to form the **glenoid cavity** (Fig. 4-135). The surface of this shallow cavity faces laterally and, in the intact body, is covered with articular cartilage for reception of the head of the humerus. Its margins or lips are covered by a fibrocartilaginous ring, the **glenoid labrum**, which broadens and deepens the cavity. At its apex, near the base of the coracoid process, is a slight elevation, the **supraglenoid tubercle**, to which the long head of the biceps brachii muscle is attached.

**STRUCTURE.** The head, processes, and thickened parts of the scapula contain cancellous bone; the rest consists of a thin layer of compact tissue. The central part of the supraspinatus and infraspinatus fossae are usually so thin as to be translucent. Occasionally the bone is even partially deficient at these sites, and the adjacent muscles are separated only by fibrous tissue.

**OSSIFICATION.** The scapula is ossified from at least seven centers: one for the body, two for the coracoid process, two for the acromion, one for the medial or vertebral border, and one for the inferior angle (Fig. 4-136).

Ossification of the body of the scapulae begins about the second month of fetal life, by the formation of an irregular quadrilateral plate of bone near the scapular neck adjacent to the glenoid cavity. This plate is extended to form the chief part of the bone, the spine growing up from its dorsal surface about the third month. At birth, a large part of the scapula is osseous, but the glenoid cavity, the coracoid process, the acromion, the vertebral border, and the inferior angle are cartilaginous. During the first year after birth an ossification center appears in the middle of the coracoid process which as a rule becomes joined with the rest of the bone about the fifteenth year. Between the fourteenth and twentieth years, ossification of the remaining parts of the scapula takes place in quick succession. During this post-puberty period, the following structures ossify in order: the root of the coracoid process, the base of the acromion, the inferior angle and contiguous part of the medial border, the extremity of the acromion, and the remainder of the medial border.

The base of the acromion is formed by an extension from the spine of the scapula. The two separate

**FIG. 4-136.** Plan of ossification of the scapula. From seven centers.

ossification centers of the acromion unite and then join with the extension from the spine. The upper third of the glenoid cavity is ossified from a separate center (subcoracoid), which makes its appearance between the tenth and eleventh years and joins between the sixteenth and eighteenth. Further, an epiphyseal plate appears for the lower part of the glenoid cavity, while the tip of the coracoid process frequently presents a separate nucleus. These various epiphyses are joined to the bone by the twenty-fifth year. Failure of bony union between the acromion and spine sometimes occurs, the junction being effected by fibrous tissue or by an imperfect articulation. In some cases of supposed fracture of the acromion with ligamentous union, it is probable that the detached segment was never united to the rest of the bone.

### THE HUMERUS

The **humerus** (Figs. 4-137 to 4-146) is the longest and largest bone of the upper limb. It extends from the shoulder joint above, where it articulates with the scapula, to the elbow joint below, where it articulates with the radius and ulna of the forearm. The humerus consists of a **body** or **shaft** and enlarged **proximal** and **distal extremities**. The proximal extremity includes a rounded **head**, a **neck**, and two tubercles, the **greater** and **lesser tubercles**. The distal extremity is condylar in form and includes the rounded **capitulum**, the grooved **trochlear**, and two **epicondyles**.

**PROXIMAL EXTREMITY.** The head (Fig. 4-137) of the humerus is nearly hemispherical in form. With the upper extremity by the

side of the body, it is directed superiorly, medially and slightly dorsally, and its smooth surface, covered with cartilage, articulates with the glenoid cavity of the scapula (Fig. 4-138). The circumference of the articular surface of the head of the humerus is slightly constricted and is termed the **anatomical neck**, in contradistinction to a constriction below—a tubercle which is called the **surgical neck** and is frequently the site of fracture. Fracture of the anatomical neck rarely occurs.

The **anatomical neck** (Figs. 4-139; 4-141; 4-142) is obliquely directed, forming an obtuse angle with the body. It is well marked in the lower half of its circumference, and in the upper half, it is represented by a narrow groove which separates the humeral head from the tubercles. The circumference of the anatomical neck affords attachment to the articular capsule of the shoulder joint, and it is perforated by numerous vascular foramina.

The **greater tubercle** (Figs. 4-137 to 4-139; 4-141; 4-142) is situated lateral to the head of the humerus and lesser tubercle. Its upper surface is rounded and marked by three flat impressions: the highest of these gives insertion to the supraspinatus muscle, the middle to the infraspinatus, and the lowest to the teres minor. The insertion of the latter muscle extends about an inch below the greater tubercle along the humeral shaft. The lateral surface of the greater tubercle is convex and rough, and merges distally into the lateral surface of the body.

The **lesser tubercle** (Figs. 4-139; 4-141), although smaller than the greater tubercle, is more prominent. It is situated anteriorly on the bone, adjacent to the anatomical neck. Its anterior surface serves for the insertion of the tendon of the subscapularis muscle.

The tubercles are separated from each other by a deep groove, the **intertubercular groove (bicipital groove)**, which lodges the tendon of the long head of the biceps brachii muscle and transmits a branch of the anterior humeral circumflex artery to the shoulder joint. The groove courses obliquely downward and ends nearly one-third of the way along the humeral shaft. In the intact body its upper part is coated with a thin layer of cartilage and enclosed by a prolongation of the synovial membrane of the shoulder joint. Its lower portion becomes shallow and receives the insertion of the

tendon of the latissimus dorsi muscle. Its lips are called, respectively, the **crests** of the **greater** and **lesser tubercles (bicipital ridges)**. Just below the two tubercles, the humerus becomes constricted to form the **surgical neck** of the humerus.

**BODY OR SHAFT.** The **body** or **shaft** of the humerus is nearly cylindrical in the upper half of its extent. It is prismatic and flattened distally, and has two borders and three surfaces (Figs. 4-139 to 4-142).

The **lateral border** (Figs. 4-139; 4-140) runs from the dorsal part of the greater tubercle to the lateral epicondyle and separates the anterolateral surface from the posterior surface. Its proximal half is rounded and indistinctly marked, serving for the attachment of part of the insertion of the teres minor, and the origin of the lateral head of the triceps brachii. Its center is traversed by a broad but shallow oblique depression, the **sulcus** or **groove for the radial nerve** (Figs. 4-140; 4-142). Its distal part forms a prominent, rough margin, the **lateral supracondylar ridge**, which presents an **anterior lip** for the origin of the brachioradialis above and extensor carpi radialis longus below, a **posterior lip** for the medial head of the triceps brachii,

and an **intermediate ridge** for the attachment of the lateral intermuscular septum.

The **medial border** (Figs. 4-139; 4-140) extends from the lesser tubercle to the medial epicondyle. Its proximal third consists of a prominent ridge, the **crest of the lesser tubercle**, which receives the insertion of the tendon of the teres major. About its center is a rough impression for the insertion of the coracobrachialis, and just distal to this is the entrance of the nutrient canal. Sometimes there is a second nutrient canal at the commencement of the radial sulcus. The distal third of this border is raised into a slight ridge, the **medial supracondylar ridge**, which becomes very prominent distally. It presents an **anterior lip** for the origin of the brachialis muscle, a **posterior lip** for the medial head of the triceps brachii, and an **intermediate ridge** for the attachment of the medial intermuscular septum.

The anterior aspect of the humerus is divided longitudinally into an **anterolateral surface** and an **anteromedial surface** by an oblique ridge beginning laterally at the greater tubercle and ending near the medial epicondyle.

The **anterolateral surface** receives the in-

FIG. 4-139. Left humerus. Ventral view. Articular capsule in blue line.

FIG. 4-140. Left humerus. Dorsal view. Articular capsule in blue line.

**FIG. 4-141.** The left humerus viewed from the anterior aspect. (From Benninghoff and Goerttler, 1975.)

section of the pectoralis major muscle along the distal part of the crest of the greater tubercle. Lateral and distal to this is an oblong area onto which inserts the deltoid muscle. At this site a rough triangular elevation, the **deltoid tuberosity**, marks the anterolateral surface. Distally there is a broad area, slightly concave, which gives origin to part of the brachialis. Beyond the deltoid tuberosity is the radial sulcus, which is directed obliquely distalward, and marks the path of the radial nerve and profunda artery.

The **anteromedial surface** proximally receives the tendon of insertion of the latissimus dorsi in the intertubercular groove. Somewhat distal and medial to this, near the

medial border, is the insertion of the teres major. At about the middle of the shaft is a rough impression for the coracobrachialis muscle. The distal part of the surface is flat and smooth, giving origin to the brachialis muscle.

The **dorsal surface** appears somewhat twisted, so that its upper part is directed a little medially, while the lower part is directed posteriorly and a little laterally. It is almost completely covered by the lateral and medial heads of the triceps brachii, the former arising proximal and the latter distal to the radial sulcus.

**DISTAL EXTREMITY.** The **distal extremity** is flat and ends inferiorly in a broad, articular surface, generally called a **condyle**, which

**FIG. 4-142.** The left humerus viewed from the posterior aspect. (From Benninghoff and Goerttler, 1975.)

**FIG. 4-143.** The lower end of the left humerus. Inferior aspect.

is divided into two parts by a slight ridge. The lateral portion of this surface consists of a smooth, rounded eminence named the **capitulum** of the humerus (Figs. 4-139; 4-141; 4-143). It articulates with the fovea on the head of the radius. On the medial side of this eminence is a shallow groove, in which is received the medial margin of the head of

the radius. Above the anterior part of the capitulum is a slight depression, the **radial fossa** (Fig. 4-139), which receives the anterior border of the head of the radius when the forearm is flexed. The medial portion of the articular surface is named the **trochlea** (Figs. 4-139; 4-141; 4-143), which occupies the anterior, inferior, and posterior surfaces of

**FIG. 4-144.** Roentgenogram of shoulder of a child aged six years. The upper arrow indicates the coracoid process; the lower arrow indicates the epiphyseal line. Note that the upper end of the diaphysis is conical and projects into the center of the epiphysis. The centers for the head of the humerus and the tuberosities have fused to form a single epiphysis. Observe also the compact nature of the bone along the surface of the humeral shaft in contrast to the inner cancellous tissue.

FIG. 4-145. Plan of ossification of the humerus.

	unite with body

the condyle. The trochlea presents a deep groove between two well-marked borders. Its lateral border is separated from the capitulum, which articulates with the margin of the head of the radius, by a fine groove. The medial border is thicker and more prominent, and projects farther distally than the lateral. The grooved portion of the articular surface fits accurately within the trochlear notch of the ulna, and it is broader and deeper on the dorsal than on the ventral aspect of the bone. Above the anterior part of the trochlea is a small depression, the **coronoid fossa** (Figs. 4-139; 4-141), which receives the coronoid process of the ulna during flexion of the forearm. Above the posterior part of the trochlea is a deep triangular depression, the **olecranon fossa**

(Figs. 4-140; 4-142), into which the summit of the olecranon is received when the forearm is extended. These fossae are separated from one another by a thin, transparent lamina of bone, which is sometimes perforated to produce a **supratrochlear foramen**. They are lined in the intact body by the synovial membrane of the elbow joint, and their margins afford attachment to the anterior and posterior ligaments of this articulation.

Projecting from both the lateral and medial aspects of the articular surface of the condyle are the **medial** and **lateral epicondyles** (Fig. 4-142). These nonarticular processes allow for the attachment of many muscles.

The **lateral epicondyle** is a small, tuberculated and curved eminence giving attachment to the radial collateral ligament of the elbow joint, and to the common tendon of origin of the supinator and extensor muscles of the forearm. The **medial epicondyle**, larger and more prominent than the lateral, gives attachment to the ulnar collateral ligament of the elbow joint, to the pronator

FIG. 4-146. Epiphyseal lines of the humerus in a young adult. Ventral aspect. The lines of attachment of the articular capsules are in blue.

teres, and to the common tendon of origin of the flexor muscles of the forearm. The ulnar nerve runs in a groove on the dorsum of the medial epicondyle. The epicondyles are continuous superiorly with the **supracondylar ridges**.

**STRUCTURE.** The extremities of the humerus consist of cancellous tissue, covered with a thin, compact layer (Fig. 4-144). The body or shaft is composed of a cylinder of compact tissue, thicker at the center than toward the extremities, and it contains a large medullary canal which extends along its whole length.

**OSSIFICATION** (Figs. 4-145; 4-146). The humerus is ossified from eight centers, one for each of the following parts—the body, the head, the greater tubercle, the lesser tubercle, the capitulum, and the trochlea—and one for each epicondyle. The center for the body appears near the middle of the bone in the eighth week of fetal life, and soon extends toward the extremities. At birth the humerus is ossified in nearly its whole length, only the extremities remaining cartilaginous. During the first year, but in some individuals before birth, ossification commences in the head of the bone. During the third year the center for the greater tubercle, and during the fifth that for the lesser tubercle, make their appearance. By the sixth year (Fig. 4-144) the centers for the head and tubercles have joined, thus forming a single large epiphysis, which fuses with the body about the twentieth year. The conical shape of the proximal end of the diaphysis, where the epiphyseal cap fits over it as shown by the epiphyseal line in Figure 4-144, is an adult condition. In the fetus and newborn, the end of the diaphysis is flat. The conical shape is established during the first year and gradually reaches its adult height by the twelfth year. The distal end of the humerus is ossified as follows: at the end of the second year ossification begins in the capitulum, and extends medially to form the chief part of the articular end of the bone; the center for the medial part of the trochlea appears about the age of ten. Ossification begins in the medial epicondyle about the fifth year, and in the lateral about the twelfth or thirteenth year. About the sixteenth or seventeenth year, the lateral epicondyle and both portions of the articulating surface, having already joined, unite with the body, and at about the eighteenth year the medial epicondyle becomes joined to it.

**VARIATIONS.** A small, hook-shaped process of bone, the **supracondylar process**, varying from 2 to 20 mm in length, is a common variation found projecting from the ventromedial surface of the body of the humerus 5 cm cranial to the medial epicondyle. Curved distally and ventrally, the pointed end of a well-developed supracondylar process may be connected to the medial epicondyle by a fibrous band that gives origin to a portion of the pronator teres. Through the arch completed by this fibrous

band, the median nerve and brachial artery may pass. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery, in cases of high division of the brachial artery. A well-marked groove is frequently found dorsal to the process, along which the nerve and artery are lodged. This arch is the homologue of the **supracondyloid foramen** found in many animals, in which it probably serves to protect the nerve and artery from compression during the contraction of the muscles in this region.

**FRACTURES OF THE HUMERUS.** Fractures of the humerus are encountered frequently and may occur at the proximal end, at the shaft, and at the distal end (Thorek, Healey and Seybold, 1966). Proximally *fractures at the anatomical neck* are rare, but they may occur in older people, and usually result from the impact of a fall on the shoulder. These fractures are intracapsular, because the articular capsule of the shoulder joint attaches to the humerus below the anatomical neck. *Fractures of the surgical neck* are more common and frequently occur from a direct impact or from falls on the elbow with the arm abducted. The distal fragment in this fracture (shaft of the humerus) is adducted or pulled medially by the attached pectoralis major, teres major, and latissimus dorsi, whereas the proximal fragment is abducted by the supraspinatus muscle. The type of injury that would cause fracture at the surgical neck in older individuals may cause a *separation of the upper humeral epiphysis* from the head of the humerus in children and adolescents prior to the time of permanent union of the epiphysis. Separation or *fracture of the greater tubercle* can result from a direct impact or from the pull of the attached supraspinatus muscle. The greater tubercle in these instances is usually pulled superiorly and posteriorly. *Fractures of the lesser tubercle* are more rare.

*Fractures of the humeral shaft* are usually the result of direct violence and generally break the bone transversely. If the fracture occurs *above* the insertion of the deltoid muscle, the upper fragment of the humerus is adducted or pulled medially by the pectoralis major, latissimus dorsi, and teres major. The lower fragment is displaced laterally by the deltoid. If the fracture occurs *below* the insertion of the deltoid, the upper fragment of the humerus becomes displaced laterally by the deltoid and supraspinatus muscles, while the lower fragment is pulled medially and upward by the triceps, biceps, and coracobrachialis muscles. Fractures of the humeral shaft endanger the radial nerve which, along with the profunda brachii artery, courses in the sulcus for the radial nerve around the body of the bone.

Distally, fractures of the humerus may involve the shaft of the humerus above the condyle. Thus, a *supracondylar fracture* occurs frequently in children who sustain a fall on the outstretched hand. The shaft of the humerus is thin just above the elbow joint, and the break results in the distal fragment of the humerus frequently being displaced posteriorly and upward (extension type). At times the distal

fragment is displaced anteriorly (flexion type). Supracondylar fractures may injure the medial nerve and brachial artery anteriorly or the radial nerve laterally. Fractures may also occur at the level of the condyle. The break in these *condylar fractures* may extend into the elbow joint and even injure the ulnar nerve which courses behind the joint.

### THE ULNA

The **ulna** (Figs. 4-147; 4-148; 4-154 to 4-156) is a long prismatic bone that occupies the medial or little finger side of the forearm and lies parallel with the radius. It is divisible into a **body** and **two extremities**. Its proximal extremity is of great thickness and strength. It is hook-like in shape and forms a large part of the elbow joint. The bone diminishes in size from above downward, so

**FIG. 4-147.** Proximal extremity of the left ulna. Lateral aspect.

that its distal extremity is quite small, and is excluded from the wrist joint by the interposition of an articular disc.

**PROXIMAL EXTREMITY.** The proximal extremity (Fig. 4-147) presents two curved processes, the **olecranon** and **coronoid processes**, and two concave, articular cavities, the **trochlear** and **radial notches**. The latter articulate, respectively, with the humerus and radius.

The **olecranon** (Figs. 4-147; 4-148; 4-156) is a large, thick, curved eminence situated on the superior and posterior part of the ulna, and forming the point of the elbow. It is bent forward at the summit so as to present a prominent lip which is received into the olecranon fossa of the humerus when the forearm is extended. The **base** of the olecranon is constricted where it joins the body of the ulna, and this is the narrowest part of the upper end of the ulna. Its **posterior surface** is triangular and smooth and can readily be palpated through the skin. It is covered by a bursa. The **superior surface** of the olecranon is quadrilateral in shape and is marked behind by a rough impression for the insertion of the triceps brachii, and in front, near the margin, by a slight transverse groove for the attachment of part of the posterior ligament of the elbow joint. Its **anterior surface** is smooth and concave, and forms the upper part of the trochlear notch. To the anterior aspect of the superior surface of the olecranon is attached the capsule of the elbow joint, while medially the olecranon affords attachment to the oblique and posterior parts of the ulnar collateral ligament. Also attached medially is the ulnar head of the flexor carpi ulnaris muscle. The lateral surface of the olecranon affords attachment to the anconeus muscle.

The **coronoid process** (Figs. 4-147; 4-148) is a triangular eminence that projects by means of its **base** from the proximal and anterior part of the body of the bone, just below the olecranon. Its **apex** is pointed, slightly curved upward, and during flexion of the forearm is received into the coronoid fossa of the humerus. The **superior surface** of the coronoid process is smooth and concave, and forms the lower part of the trochlear notch. Its **inferior surface** is concave and rough, and at its junction with the front of the body is a rough eminence, the **tuberosity of the ulna**, which gives insertion to the brachialis muscle and the ligamentous oblique cord of the radius. Its **lateral surface**

**Fig. 4-148.** The bones of the left forearm. Anterior aspect. Attachment of articular capsules outlined in blue.

presents a narrow, oblong, articular depression, the **radial notch**. Its **medial surface**, by its prominent, free margin, serves for the attachment of the anterior and oblique parts of the ulnar collateral ligament. At the front part of the medial surface is a small rounded

eminence for the origin of the humeroulnar head of the flexor digitorum superficialis. Behind the eminence descends a ridge from which arises the uppermost fibers of the flexor digitorum profundus, along with the ulnar head of the pronator teres. A small

ulnar head of the flexor pollicis longus may arise from the distal part of the coronoid process by a rounded bundle of muscular fibers.

The **trochlear notch** (Figs. 4-147; 4-148) is a large depression which is semilunar in shape and formed by the coronoid process and the olecranon. It serves for articulation with the trochlea of the humerus. The borders of the notch are indented near its middle, thereby subdividing the articular surface into a proximal olecranon part and a distal coronoid part. Additionally, the notch is divided by a longitudinal ridge into a larger medial and a smaller lateral part.

The **radial notch** (Figs. 4-147; 4-148) is a narrow, oblong, articular depression on the lateral side of the coronoid process. It receives the circumferential articular surface of the head of the radius. The anterior and posterior margins of its concave surface afford attachment of the annular ligament. Radiographically, the proximal extremity of the ulna can be seen in Figures 4-151 to 4-153.

**BODY OR SHAFT.** The **body or shaft** (Figs. 4-148; 4-154 to 4-156) is prismatic, or three-sided, in its upper two-thirds, but then becomes rounded or cylindrical distally. It is curved so as to be convex dorsally and laterally. Its central part is straight, its distal part a little concave lateralward. It tapers gradually and presents *anterior, posterior, and interosseous borders* as well as *anterior, posterior, and medial surfaces*.

The **anterior border** begins above at the prominent medial angle of the coronoid process and ends below in front of the styloid process. Its proximal part is well defined, and its middle portion is smooth and rounded, giving origin to the flexor digitorum profundus muscle. The distal one-fourth of the anterior surface is called the **pronator ridge**, which serves for the origin of the pronator quadratus. This border separates the anterior from the medial surface.

The **posterior border** begins above at the apex of the triangular subcutaneous surface of the olecranon, and ends below at the back of the styloid process. It is well marked in the proximal three-fourths, and gives attachment to an aponeurosis which affords a common origin to the flexor carpi ulnaris, the extensor carpi ulnaris, and the flexor digitorum profundus. Its distal one-fourth is smooth and rounded. This border separates the medial from the posterior surface.

The **interosseous border** (Figs. 4-147; 4-154; 4-155) is actually the lateral margin of the ulna. The union proximally of two lines that converge from the extremities of the radial notch form a sharp, prominent crest along the middle two-fourths of this border. In the upper part the converging lines enclose between them a triangular space for the origin of part of the supinator muscle. One of these lines descends from the medial margin of the radial notch and is called the **supinator crest** (Fig. 4-147). Thus, the proximal part of the interosseous border is sharp, while its distal one-fourth is smooth and rounded. The interosseous border gives attachment to the interosseous membrane and separates the anterior from the posterior surface.

The **anterior surface** (Figs. 4-148; 4-154) is concave in its upper three-fourths. This surface is much broader proximally where it gives origin to the flexor digitorum profundus. Its distal fourth, covered by the pronator quadratus, is separated from the remaining portion by an oblique ridge, which marks the extent of origin of the pronator quadratus (Fig. 4-148). At the junction of the proximal with the middle third of the bone is the nutrient canal, which is directed upward and contains a branch of the anterior interosseous artery.

The **posterior surface** (Figs. 4-155; 4-156) of the ulna is broad and concave above, convex and somewhat narrower in the middle, and narrow, smooth, and rounded distally. This surface is marked by an oblique ridge which commences proximally at the dorsal end of the radial notch and courses distally. The triangular surface proximal to this ridge receives the insertion of the anconeus, while the proximal part of the ridge affords attachment to the supinator. Distally, the surface is subdivided into two parts by another longitudinal ridge, sometimes called the **perpendicular line**: the medial part is smooth and covered by the extensor carpi ulnaris; the lateral part, wider and rougher, gives origin to the supinator, the abductor pollicis longus, the extensor pollicis longus, and the extensor indicis (Fig. 4-156).

The **medial surface** of the ulna is broad and concave proximally, but narrow and convex distally. Its proximal three-fourths give origin to the flexor digitorum profundus; its distal one-fourth is subcutaneous.

**DISTAL EXTREMITY.** The **distal extremity** of the ulna (Figs. 4-148; 4-154 to 4-156) is smaller

than the proximal extremity and it presents two eminences. Of the two, the lateral is larger, and it is a rounded, articular eminence, termed the **head of the ulna**. The medial eminence is the narrower, more projecting, nonarticular **styloid process**. The head of the ulna articulates with the proximal surface of a triangular articular disc which separates it from the wrist joint. The remaining portion of the ulnar head is received into the ulnar notch of the radius. The styloid process projects from the medial and posterior part of the bone. It descends a little lower than the head of the ulna, and its rounded end affords attachment to the ulnar collateral ligament of the wrist joint. The head is separated from the styloid process by a depression on which attaches the apex of the triangular articular disc. Posteriorly, these two eminences are separated by a shallow groove for the tendon of the extensor carpi ulnaris.

**STRUCTURE.** The long, narrow medullary cavity is enclosed in a strong wall of compact tissue, which is thickest along the interosseous border and dorsal surface. At the extremities the compact layer becomes thinner and is continued onto the back of the olecranon as a plate of close spongy bone with parallel lamellae. From the inner surface of this plate and the compact layer distal to it, trabeculae arch toward the olecranon and coronoid, and cross other trabeculae passing posteriorly over the medullary cavity from the proximal part of the shaft distal to the coronoid process. Distal to the coronoid process there is a small area of compact bone from which trabeculae curve proximally to end oblique to the surface of the trochlear notch, which is coated with a thin layer of compact bone. The trabeculae at the distal end have more longitudinal direction.

**OSSIFICATION** (Figs. 4-149; 4-150). The ulna is ossified from three centers: one each for the body or shaft, the distal extremity, and the proximal portion of the olecranon. Ossification begins near the middle of the shaft about the eighth week of fetal life and soon extends through the greater part of the bone. At birth the distal extremity and the greater part of the olecranon are cartilaginous. Between the fifth and sixth years, a center appears in the middle of the ulnar head and soon extends into the styloid process. About the tenth year, a center appears in the olecranon near its extremity. The major portion of the olecranon that is being ossified develops from a proximal extension of the ossification center in the shaft. The proximal epiphysis joins the body about the sixteenth year, while the distal extremity unites with the shaft about the twentieth year.

**ARTICULATIONS.** The ulna articulates with the humerus and radius. Although it is customary to exclude the ulna from the wrist joint because of the

**Fig. 4-149.** Epiphyseal lines of ulna in a young adult. Lateral aspect. The lines of attachment of the articular capsules are in blue.

**Fig. 4-150.** Plan of ossification of the ulna. From three centers.

intervention of the articular disc, it should be appreciated that it contributes to this joint in much the same way as the clavicle does to the sternoclavicular and the mandible to the temporomandibular joints.

### THE RADIUS

The **radius** (Figs. 4-148; 4-154 to 4-156) lies parallel with the ulna and is on the lateral, or thumb, side of the forearm. It is shorter than the ulna, and although both ends are expanded, the proximal end is smaller than the distal. The radius participates in forming the elbow joint, and it is the chief proximal bone in the formation of the wrist joint. It presents a body or shaft and two extremities.

**PROXIMAL EXTREMITY.** The proximal extremity presents a head, neck, and tuberosity. The **head** is cylindrical, and on its proximal surface is a shallow cup or **fovea** for articulation with the capitulum of the humerus. The **articular circumference** of the head is smooth. It is broad medially where it articulates with the radial notch of the ulna, narrow in the rest of its extent where it is embraced by the annular ligament. The head is supported on a round, smooth, and constricted portion called the **neck**, on the back of which is a slight ridge for the insertion of part of the supinator. Distal to the medial part of the neck is an oval eminence, the **radial tuberosity**. Its surface is divided into a posterior, rough portion, for the insertion of the tendon of the biceps brachii muscle, and an anterior, smooth portion, on which a bursa is interposed between the tendon and the bone. Radiographs of the proximal extremity of the radius can be seen in Figures 4-151 to 4-153.

**BODY OR SHAFT.** The **body** or **shaft** is round or cylindrical above where it joins the neck, but becomes triangular or prismatic in shape more distally. It also gradually increases in size from above downward. The radius is gently curved, so that it is convex laterally, and it presents three borders and three surfaces.

The **anterior border** extends from the lower part of the tuberosity to the anterior part of the base of the styloid process, and separates the anterior from the lateral surface. Its proximal third is elevated to form the **anterior oblique line of the radius** (Fig. 4-148), which gives origin to the flexor digitorum superficialis and flexor pollicis longus muscles. The surface proximal to the

**Fig. 4-151.** Adult elbow. Frontal view. The shadow of the olecranon extends upward to the olecranon fossa and obscures the outline of the trochlea. The gap between the humerus and the bones of the forearm is occupied by the articular cartilage of the bones concerned.

oblique line receives the insertion of part of the supinator muscle. The middle portion of the anterior border is rounded and less distinct, but the distal one-fourth receives the insertion of the pronator quadratus, and attachment of the dorsal carpal ligament. It ends in a small tubercle, into which the tendon of the brachioradialis muscle is inserted.

The **posterior border** begins proximally at the posterior aspect of the neck and ends distally at the posterior part of the base of the styloid process. It separates the posterior from the lateral surface. This border is rounded and indistinct near the extremities, but well marked in the middle third of the bone.

The **interosseus border** is rounded and indistinct where it begins above at the radial tuberosity. It becomes sharp and prominent as it descends, and at its distal part divides

**FIG. 4-152.** Elbow of a child aged 11 years. Frontal view. The upper epiphysis of the radius, the epiphysis for the medial epicondyle, and the center for the capitulum and the lateral part of the trochlea can be recognized.

into two ridges which are continued to the anterior and posterior margins of the ulnar notch. The triangular surface between the ridges receives the insertion of part of the pronator quadratus muscle. This border separates the anterior from the posterior surface of the bone, and gives attachment to the interosseous membrane, which interconnects the opposed borders of the radius and ulna.

The **anterior surface** (Figs. 4-148; 4-154) is concave in its proximal three-fourths, and gives origin to the flexor pollicis longus. It is broad and flat in its distal one-fourth, and receives the insertion of the pronator quadratus. A prominent ridge limits the insertion of the pronator quadratus distally, and between this and the inferior edge of the radius is a triangular rough surface for the attachment of the palmar radiocarpal ligament. At the level of the junction of the upper and middle third of the anterior surface is the nutrient foramen which transmits a branch of the anterior interosseous artery to the bone.

The **posterior surface** of the radius (Figs. 4-155; 4-156) is convex and smooth in the proximal third of its extent, and covered by the supinator. Its middle third is broad, slightly concave, and gives origin to the abductor pollicis longus and extensor pollicis brevis muscles. Its distal third is broad, convex, and covered by the tendons of the muscles that subsequently run in grooves along

**FIG. 4-153.** Elbow of a child aged 10 years. Lateral view. The upper epiphysis of the radius, the olecranon epiphysis, and the center for the capitulum and the lateral part of the trochlea can be observed.

**FIG. 4-154.** Left forearm bones. Anterior aspect. (From Benninghoff and Goerttler, 1975.)

the dorsal aspect of the distal extremity. These are described below.

The **lateral surface** is convex throughout its entire extent. Its upper third receives the insertion of the supinator. About its center is a rough ridge for the insertion of the pronator teres muscle. Its lower part is narrow and covered by the tendons of the abductor pollicis longus and extensor pollicis brevis muscles.

**DISTAL EXTREMITY.** The distal extremity of the radius (Figs. 4-148; 4-154; 4-156) is quadrilateral in shape and is the broadest portion of the bone. It is provided with two articular surfaces—one on the distal end of the bone articulates with the carpal bones at the wrist joint; the other is directed medially for articulation with the ulna. The **carpal articular surface** (Fig. 4-157) is concave and smooth, and it is divided by a slight anteroposterior ridge into lateral and medial parts. Of these,

the lateral is somewhat triangular in shape and it articulates with the scaphoid bone, while the medial is more quadrangular in shape and it articulates with the lunate bone. The articular surface for the ulna is called the **ulnar notch of the radius**. It is narrow, smooth, and concave, and articulates with the head of the ulna to form the inferior radioulnar joint.

The two articular sites on the distal extremity of the radius are separated by a prominent ridge, to which is attached the base of the triangular articular disc which lies between the wrist joint and the distal radioulnar articulation. The distal extremity also presents three nonarticular surfaces: anterior, posterior, and lateral. The palmar or **anterior surface**, rough and irregular, affords attachment to the palmar radiocarpal ligament. The **posterior surface** is convex and affords attachment to the dorsal radiocarpal ligament. Near its middle, this surface

**FIG. 4-155.** Left forearm bones. Posterior aspect. (From Benninghoff and Goerttler, 1975.)

FIG. 4-156. The bones of the left forearm. Posterior aspect. Attachment of articular capsules outlined in blue.

**FIG. 4-157.** The distal ends of the left radius and ulna showing the carpal articular surface of the radius and the area on the ulna for contact with the articular disc. Inferior aspect.

is marked by a **dorsal tubercle** (Fig. 4-157), to which is attached a part of this extensor retinaculum. Further, this surface contains three grooves within which lie tendons of muscles of the extensor forearm compartment. Beginning at the lateral or thumb side, the first groove is broad but shallow, and subdivided into two parts by a slight ridge; the lateral part transmits the tendon of the extensor carpi radialis longus, the medial transmits the tendon of the extensor carpi radialis brevis. The second groove is deep but narrow and bounded laterally by a sharply defined oblique ridge; it transmits the tendon of the extensor pollicis longus. The third is broad, for the passage of the tendons of the extensor digitorum. Deep to these tendons and adjacent to the bone course the tendon of the extensor indicis and the posterior interosseous nerve. The **lateral surface** is prolonged distally into a strong, conical projection, the **styloid process**. This process extends distally beyond the ulnar styloid process and gives attachment by its base to the tendon of the brachioradialis, and by its apex to the radial collateral ligament of the wrist joint. The lateral surface of the styloid process of the radius is marked by a flat groove for the tendons of the abductor pollicis longus and extensor pollicis brevis.

**STRUCTURE.** The long narrow medullary cavity of the radius is enclosed in a strong wall of compact tissue, which is thickest along the interosseous border and thinnest at the extremities except over the cup-shaped articular surface of the head, where it is

thick. The trabeculae of the spongy tissue are somewhat arched at the proximal end and pass proximally from the compact layer of the shaft to the fovea of the head of the radius. They are crossed by other trabeculae which are oriented parallel to the surface of the fovea. The arrangement at the distal end is somewhat similar.

**OSSIFICATION** (Figs. 4-158; 4-159). The radius is ossified from three centers: one for the body and one for each extremity. That for the shaft makes its appearance near the center of the bone during the

**FIG. 4-158.** Plan of ossification of the radius. From three centers.

**Fig. 4-159.** Epiphyseal lines of radius in a young adult. Anterior aspect. The line of attachment of the articular capsules of the wrist joint is in blue.

eighth week of fetal life. During the second year, ossification commences in the distal end, and at about the fifth year, in the proximal end. The proximal epiphysis fuses with the body at the age of fifteen to eighteen years, while the distal epiphysis fuses between the seventeenth and twentieth year. An additional center sometimes found in the radial tuberosity appears about the fourteenth or fifteenth year.

**ARTICULATIONS.** The radius articulates with the humerus, ulna, scaphoid, and lunate bones.

### The Hand

The skeleton of the hand (Figs. 4-160; 4-161) is subdivided into three segments: the **carpal** or wrist bones, the **metacarpal** bones of the palm, and the **phalanges** or bones of the digits.

### CARPAL BONES

The **carpal bones** are eight in number and they are arranged in two rows of four bones each. Those of the proximal row, from the radial to the ulnar side, are named the **scaphoid**, **lunate**, **triquetral**, and **pisiform**;

those of the distal row, in the same order, are named the **trapezium**, **trapezoid**, **capitate**, and **hamate**.

**SURFACES OF THE CARPAL BONES.** With the exception of the pisiform bone which lies on the palmar surface of the triquetral, each carpal bone has six surfaces: palmar and dorsal, proximal and distal, medial and lateral. The **palmar** (volar) and **dorsal** surfaces are roughened for ligamentous attachment, the dorsal surfaces generally being broader than the palmar, except for the scaphoid and lunate. The **proximal** and **distal** surfaces are articular, the proximal generally being convex and the distal concave. The **medial** (ulnar) and **lateral** (radial) surfaces are also

**Fig. 4-160.** Outline of the left hand, showing the skeleton from the dorsal aspect. (From Benninghoff and Goertler, 1975.)

**FIG. 4-161.** Outline of the left hand, showing the skeleton from the palmar aspect. (From Benninghoff and Goertler, 1975.)

articular and the means by which the carpal bones articulate with each other, allowing the formation of the two rows of contiguous bones characteristic of the human carpus.

#### BONES OF THE PROXIMAL ROW

The bones of the proximal row are so oriented that their proximal and distal surfaces form an arch, the convexity of which is directed proximally for articulation with the radius and the articular disc capping the lower end of the ulna. The concavity of this arch, directed distally, is filled principally by the capitate and hamate of the distal row of carpal bones (Figs. 4-160; 4-161). The dorsal surface of the bones in the proximal row

is slightly convex and uneven, and it is covered by ligaments and tendons. The volar surface is concave, contributing to the **carpal groove** which is filled by structures entering the palm of the hand from the forearm. The scaphoid, lunate, triquetral, and pisiform bones will be described in order.

**SCAPHOID BONE.** The scaphoid bone (Fig. 4-162) is the largest bone of the proximal row. Its long axis extends obliquely distally and laterally and it is situated at the radial side of the carpus. The **proximal surface** is convex, smooth, and triangular, and articulates with the radius. The **distal surface** is also smooth, convex, and triangular, and is divided by a slight ridge into two parts, the lateral articulating with the trape-

FIG. 4-162. The left scaphoid bone. A, From the dorsal aspect. B, From the palmar aspect.

zium, the medial with the trapezoid. On the **dorsal surface** is a narrow, rough groove, which courses the entire length of the bone and serves for the attachment of ligaments. The **palmar surface** is concave and elevated at its lateral part into a rounded projection, the **tubercle**, to which is attached the flexor retinaculum and sometimes the origin of a few fibers of the abductor pollicis brevis. The tubercle can be felt through the skin on the anterior aspect of the extended wrist at the base of the thenar eminence and in line with the radial aspect of the middle finger. The **lateral surface** is rough and narrow, and gives attachment to the radial collateral ligament of the wrist. The **medial surface** presents two articular facets. Of these, the proximal is smaller, flattened, and of semilunar form, and articulates with the lunate bone, while the distal is concave, forming with the lunate a concavity for the head of the capitate bone.

**Articulations.** The scaphoid articulates with five bones: the radius proximally, trapezium and trapezoid distally, and capitate and lunare medially.

**Fracture of the Scaphoid.** The scaphoid is the most commonly fractured bone in the wrist. A fall upon the radially deviated hand may result in a fracture across the middle of the bone at its narrowest site.

**LUNATE BONE.** The lunate bone (Fig. 4-163) may be distinguished by its deep concavity and crescentic outline. It is situated in the center of the proximal row of carpal bones, between the scaphoid and triquetral. The **proximal surface**, convex and smooth, articulates with the radius. The **distal surface** is deeply concave and articulates with the head of the capitate. This surface also articulates with the edge of the hamate bone by a long, narrow facet which is separated from the capitate articular surface by a curved

ridge. The **dorsal** and **palmar surfaces** are both roughened for the attachment of ligaments. The **lateral surface** presents a narrow, flattened, semilunar facet for articulation with the scaphoid. The **medial surface** is marked by a smooth, quadrilateral facet for articulation with the triquetral bone.

**Articulations.** The lunare articulates with five bones: the radius proximally, capitate and hamate distally, scaphoid laterally, and triquetral medially.

**Dislocation of the Lunare.** The lunare bone is the carpal bone that is most frequently dislocated. It usually results from a fall upon the hyperextended hand in which all the other bones in the wrist are carried backward by the force of the fall except the lunare and part of the scaphoid.

**TRIQUETRAL BONE.** The triquetral bone (Fig. 4-164) may be distinguished by its pyramidal shape, and by an oval isolated facet for articulation with the pisiform bone. It is situated at the proximal and ulnar side of the wrist. The **proximal surface** presents a medial, rough, nonarticular portion, and a lateral convex articular portion which articulates with the triangular articular disc of the distal radioulnar joint of the wrist. The **distal surface**, directed lateralward, is concave, sinuously curved, and smooth for articulation with the hamate. The **dorsal surface** is rough for the attachment of ligaments. The

FIG. 4-163. The left lunate bone. A, From the infero-medial aspect. B, From the superolateral aspect.

**FIG. 4-164.** The left triquetrum bone. From the palmar aspect.

**palmar surface** presents, on its medial part, an oval facet for articulation with the pisiform, while its lateral part is rough for ligamentous attachment. The **lateral surface**, which forms the base of the pyramid, is marked by a flat, quadrilateral facet for articulation with the lunate. The roughened **medial surface** is the pointed summit of the pyramid, and to it attaches the ulnar collateral ligament of the wrist.

**Articulations.** The triquetrum articulates with three bones: the lunate laterally, the pisiform anteriorly, and the hamate distally, and with the triangular articular disc, which separates it from the lower end of the ulna proximally.

**PISIFORM BONE.** The pisiform bone (Fig. 4-165) is the smallest of the carpal bones and can be identified by its spheroidal shape, which is flat on the one surface that serves as its only articular facet. It is situated on a plane anterior to the other carpal bones, at the base of the hypothenar eminence on the medial side of the wrist. Its **dorsal surface** presents a smooth, **oval facet** for articulation with the triquetrum bone. This facet approaches the proximal but not the distal border of the bone. The **palmar surface** is rounded and rough, and gives attachment to the flexor retinaculum and to the flexor carpi ulnaris and abductor digiti minimi muscles. The **lateral and medial surfaces** are also rough, and the lateral surface usually presents a shallow groove which lies in relation to the ulnar artery.

**Articulation.** The pisiform articulates with one bone, the triquetrum. It does not participate in the formation of the radiocarpal joint.

**FIG. 4-165.** The left pisiform bone. From the dorsal aspect.

## BONES OF THE DISTAL ROW

The four **bones of the distal row** (Figs. 4-160; 4-161) articulate proximally with the scaphoid, lunate, and triquetrum, distally with the five metacarpal bones and with each other. Their arrangement is such that they form a gentle convex arch dorsally, but a deep concavity, the carpal groove, on the palmar surface. They are straighter in their alignment across the wrist than the proximal row, especially at their distal articulations with the metacarpal bones. From radial to ulnar sides, they include the trapezium, trapezoid, capitate, and hamate.

**THE TRAPEZIUM.** The trapezium (Fig. 4-166) is quite irregular in its shape, but may be distinguished by a deep groove and a distinct ridge or tubercle on its palmar surface. The bone is situated at the radial side of the wrist between the scaphoid and first metacarpal. The **proximal surface** is smooth and contains a shallow facet which articulates with the scaphoid bone. The **distal surface** is oval and saddle-shaped, and articulates with the base of the first metacarpal bone. The **dorsal surface** is rough and rests in relationship to the overlying radial artery. The **palmar surface** is narrow and rough. At its proximal part is a deep groove that transmits the tendon of the flexor carpi radialis. It is bounded laterally by an oblique, ridge-like **tubercle**. This surface gives origin to the opponens pollicis, abductor pollicis brevis, and flexor pollicis brevis muscles, and affords attachment to the flexor retinaculum. The **lateral surface** is broad and rough for the attachment of ligaments. The **medial surface** presents two facets: a large, concave, proximal one, which articulates with the trapezoid, and a small, oval, distal one, which articulates with the base of the second metacarpal.

**Articulations.** The trapezium articulates with four bones: the scaphoid proximally, the first metacarpal distally, and the trapezoid and second metacarpal medially.

**TRAPEZOID BONE.** The trapezoid bone (Fig. 4-167) is the smallest bone in the distal row. It may be identified by its wedge shape, the broad end of the wedge constituting the dorsal surface, and the narrow end forming the palmar surface of the bone. Additionally, the trapezoid has four articular facets touching each other, and these are separated by

**FIG. 4-166.** The left trapezium. A, From the palmar aspect. B, From the superomedial aspect.

sharp edges. The **proximal surface** articulates with the scaphoid. The **distal surface** is subdivided by an elevated ridge into two unequal facets, which articulate with the base or proximal end of the second metacarpal bone. The large **dorsal** and smaller **palmar surfaces** are rough for the attachment of ligaments. The **lateral surface**, convex and smooth, articulates with the trapezium. The **medial surface** is concave and smooth anteriorly for articulation with the capitate bone, but rough dorsally for the attachment of an interosseous ligament.

**Articulations.** The trapezoid articulates with four bones: the scaphoid proximally, second metacarpal distally, trapezium laterally, and capitate medially.

**CAPITATE BONE.** The **capitate bone** (Fig. 4-168) is the largest of the carpal bones and occupies the center of the wrist. It presents a rounded portion or **head**, which is received into the concavity formed by the scaphoid and lunate bones, a constricted portion or **neck**, and a **body**. The **proximal surface** is round and smooth and articulates with the lunate. The **distal surface** is divided by two ridges into three facets, which articulate with the bases of the second, third, and fourth metacarpal bones, that for the third being the largest. The **dorsal surface** is broad and rough. The **palmar surface** is narrow, rounded, and rough for the attachment of ligaments and a part of the oblique head of

the adductor pollicis muscle. The **lateral surface** articulates with the trapezoid by a small facet at its anterior inferior angle, behind which is a rough depression for the attachment of an interosseous ligament. Proximal to this is a deep, rough groove, forming part of the neck, and serving for the attachment of ligaments. Proximally, the lateral surface is bounded by a smooth, convex surface for articulation with the scaphoid. The **medial surface** articulates with the hamate by a smooth, concave, oblong facet, which occupies its proximal and more dorsal part. The palmar portion of the medial surface is rough for the attachment of an interosseous ligament.

**Articulations.** The capitate articulates with seven bones: the scaphoid and lunate proximally; the second, third, and fourth metacarpals distally; the trapezoid on the radial side, and the hamate on the ulnar side.

**Clinical Note.** The large size and central location of the capitate bone places its head in a position to transmit the force of a fall on the outstretched hand to the radius through the scaphoid and lunate bones. Thus, it is through the capitate bone that the most common injuries to the carpal bones occur, i.e., fractures of the scaphoid and dislocations of the lunate.

**HAMATE BONE.** The **hamate bone** (Fig. 4-169) is wedge-shaped and may readily be distinguished by the hook-like process that projects from its palmar surface. This bone is situated most medially along the distal row of the carpus, and the base of the wedge is directed distally and rests on the fourth and fifth metacarpal bones. The **proximal surface** is narrow, convex, and smooth, and is the apex of the wedge, articulating with the lunate. The **distal surface** articulates with the fourth and fifth metacarpal bones by concave facets that are separated by a ridge. The **dorsal surface** is triangular and rough for ligamentous attachment. The **pal-**

**FIG. 4-167.** The left trapezoid bone. A, From the medial aspect. B, From the inferolateral aspect.

FIG. 4-168. The left capitate bone. A, From the lateral aspect. B, From the medial aspect.

mar surface presents a curved hook-like process, the **hamulus**, at its distal and ulnar side. The hamulus can be felt through the skin at the base of the hypothenar eminence in line with the ulnar border of the ring finger. To the tip of the hamulus is attached the flexor retinaculum and the flexor carpi ulnaris, and to its medial surface, the flexor digitorum brevis and opponens digiti minimi. Its lateral side is grooved for the passage of the flexor tendons into the palm of the hand. It is one of the four eminences on the front of the carpus to which the flexor retinaculum of the wrist is attached; the others being the pisiform medially, the oblique ridge of the trapezium, and the tubercle of the scaphoid laterally. The **ulnar surface** of the hamate articulates with the triquetral bone by an oblong facet. The **radial surface** articulates with the capitate by its proximal and more posterior part, the remaining portion being rough for the attachment of ligaments.

**Articulations.** The hamate articulates with five bones: the lunate proximally, the fourth and fifth metacarpals distally, the triquetral medially, and the capitate laterally.

## METACARPAL BONES

**COMMON CHARACTERISTICS.** The **metacarpus** (Figs. 4-160; 4-161; 4-170 to 4-176) consists of five slender bones which are numbered 1 to 5 from the radial or thumb side to the ulnar or little finger side. Consisting of a body or shaft and two extremities, the metacarpal bones might be described as long bones in miniature. Each extends from the carpal bones to the proximal phalanx of the respective finger.

They can be palpated throughout their entire extent on the dorsum of the hand, and they terminate distally at the proximal row of knuckles. On the palmar side, they are difficult to palpate proximally since they course beneath the flexor tendons, but at a site 2 cm proximal to the roots of the fingers, they can easily be felt on the palmar surface. This site on the palm of the hand lies opposite the knuckle on the dorsum of the hand. Each metacarpal consists of a **body**, a **base**, and a **head**.

The body is curved longitudinally so as to be slightly convex on the dorsal surface, the concavity on the palmar side containing muscles. The metacarpal body presents

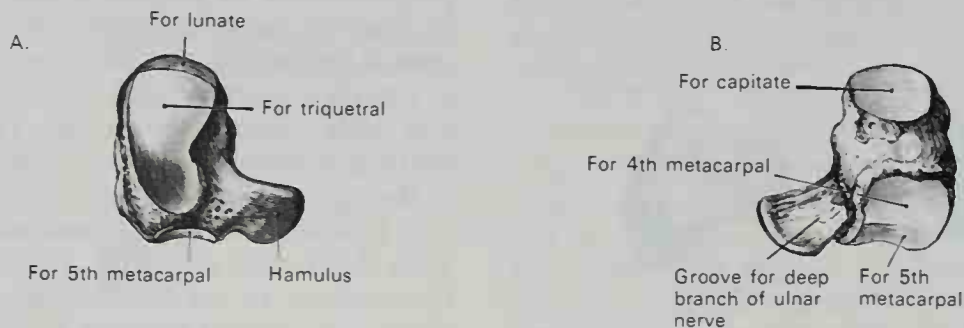

FIG. 4-169. The left hamate bone. A, From the medial aspect. B, From the inferolateral aspect.

FIG. 4-170. Bones of the left hand. Palmar surface.

three surfaces: medial, lateral, and dorsal. The **medial** and **lateral surfaces** are concave for the attachment of the interosseous muscles, and these surfaces are separated from one another by a prominent palmar ridge. The **dorsal surface** presents in its distal two-thirds a smooth, triangular, flattened area, which is covered in the intact body by

the tendons of the extensor muscles. This surface is bounded by two lines which commence as small tubercles on each side of the distal extremity. These lines converge some distance proximal to the center of the bone to form a ridge that runs along the rest of the dorsal surface to the proximal extremity. This ridge separates two sloping surfaces for

FIG. 4-171. Bones of the left hand. Dorsal surface.

the attachment of the dorsal interosseous muscles. To the tubercles on the distal extremities are attached the collateral ligaments of the metacarpophalangeal joints.

The **base** or **proximal extremity** is the expanded carpal end of the bone and is cuboi-

dal in shape but broader dorsally. It articulates proximally with the carpus, and on each side with the adjacent metacarpal bones. An exception is the base of the first metacarpal, which does not articulate with the second. The dorsal and palmar surfaces

**FIG. 4-172.** The left first metacarpal. A, Lateral or radial aspect. B, Medial or ulnar aspect.

of the metacarpal bases are rough for the attachment of ligaments.

The **head** or **distal extremity** articulates with the proximal phalanx on each finger. It presents a smooth, oblong, convex surface flattened from side to side, which extends farther proximally on the palmar than on the dorsal aspect. On each side of the head is a **tubercle**, and between the tubercles on the palmar side, a hollow fossa for the attachment of the collateral ligament of the metacarpophalangeal joint. The dorsal surface is broad and flat and supports the extensor tendons. The palmar surface is grooved in the midline for the passage of the flexor tendons and it is marked on each side by an articular eminence continuous with the terminal articular surface.

**FIRST METACARPAL BONE.** The **first metacarpal bone** (to the thumb) is shorter and stouter, and diverges to a greater degree from the carpus than the other metacarpals (Fig. 4-172). It is rotated about its long axis so that its flexor surface is directed medially toward the radial side of the second metacarpal. The **body** is flattened and broad, and its dorsal surface is slightly convex. Its palmar surface is concave and divided by a blunt ridge into a larger lateral part, which gives rise to the *opponens pollicis* muscle (Fig. 4-170), and a smaller medial part, which gives origin to the lateral head of the first dorsal interosseous muscle (Fig. 4-171). The **base** or proximal extremity presents a saddle-shaped surface for articulation with the trapezium (Fig. 4-172). It has no facets on its sides, but on its lateral side is a small tuber-

cle for the insertion of the *abductor pollicis longus*. The **head** is rounded and less convex than those of the other metacarpal bones, and is broader from side to side, than from palmar to dorsal surface. On its palmar surface of the head are two articular eminences, of which the lateral is larger, for the two sesamoid bones in the tendons of the two heads of the *flexor pollicis brevis*.

**SECOND METACARPAL BONE.** The **second metacarpal bone** (Fig. 4-173) is the longest, and its **base** the largest of all the metacarpal bones. The medial aspect of its base is prolonged proximally, thereby forming a prominent groove. On the base are four articular facets, three on the proximal surface and one, for articulation with the third metacarpal bone, on the ulnar side. Of the facets on the proximal surface the intermediate is the largest and is for articulation with the trapezoid bone. The facet on the lateral aspect of the base is flat and oval for articulation with the trapezium, while the one on the medial aspect is long and narrow for articulation with the capitae.

The *extensor carpi radialis longus* is inserted on the dorsal surface and the *flexor carpi radialis* on the palmar surface of the base (Figs. 4-171; 4-172). Along the **body** of the second metacarpal bone originate three

**FIG. 4-173.** The left second metacarpal. A, Dorsolateral aspect. B, Medial aspect.

interosseous muscles, two dorsal and one palmar. The convex, rounded **head** articulates with the proximal phalanx of the index finger.

**THIRD METACARPAL BONE.** The **third metacarpal bone** (Fig. 4-174) is a little smaller than the second. The dorsal aspect of its **base** presents on its radial side a pyramidal eminence, the **styloid process**, which extends proximally behind the capitate bone. Immediately distal to this is a rough surface on the dorsal aspect of the base for the insertion of the extensor carpi radialis brevis muscle. The base articulates by means of a concave facet with a single carpal bone, the capitate. On the radial side is a smooth, concave facet for articulation with the second metacarpal, and on the ulnar side two small oval facets for the fourth metacarpal. The dorsal surface of the **body** gives origin to the second and third dorsal interosseous muscles, while along the palmar surface arises the transverse head of the adductor pollicis muscle. The **head** of the bone articulates with the proximal phalanx of the middle finger.

**FOURTH METACARPAL BONE.** The **fourth metacarpal bone** (Fig. 4-175) is shorter and more slender than the third. The **base** is

**FIG. 4-174.** The left third metacarpal. A, Lateral aspect. B, Medial aspect.

**FIG. 4-175.** The left fourth metacarpal. A, Lateral aspect. B, Medial aspect.

small and quadrilateral, and its proximal surface presents two facets, the larger of which is oriented medially for articulation with the hamate, while the smaller one is lateral for the capitate. On the lateral aspect of the head are two oval facets for articulation with the third metacarpal, and on the medial side is found a single concave facet for the fifth metacarpal. The thin **body** gives attachment to two dorsal interosseous muscles and one palmar interosseous. The **head** articulates with the proximal phalanx of the ring finger.

**FIFTH METACARPAL BONE.** The **fifth metacarpal bone** (Fig. 4-176) presents on its **base** a concave facet on its proximal surface that articulates with the hamate, and another on its lateral side that articulates with the fourth metacarpal. Unlike all the other metacarpal bones, the medial or ulnar side of the base is nonarticular, but does present a prominent **tubercle** for the insertion of the tendon of the extensor carpi ulnaris. The dorsal surface of the **body** is divided by an oblique ridge, lateral to which arises the fourth dorsal interosseous muscle (Fig. 4-171), and medial to which course the extensor tendons of the little finger. The palmar surface of the body gives origin laterally to the third palmar interosseous muscle and insertion medially to the opponens digiti minimi muscle (Fig. 4-170).

**FIG. 4-176.** The fifth left metacarpal. A, Lateral aspect. B, Medial aspect.

**ARTICULATIONS.** Besides their phalangeal articulations, the metacarpal bones articulate as follows: the **first** with the trapezium; the **second** with the trapezium, trapezoid, capitate, and third metacarpal; the **third** with the capitate, and the second and fourth metacarpals; the **fourth** with the capitate, hamate, and third and fifth metacarpals; and the **fifth** with the hamate and fourth metacarpal.

#### PHALANGES OF THE HAND

The **phalanges** of the hand (Figs. 4-160; 4-161; 4-170; 4-171) are fourteen in number, three for each finger, and two for the thumb. The phalanges of the four fingers contain three bones called **proximal**, **middle**, and **distal**. The two of the thumb are called proximal and distal. Each phalanx consists of a **body** and two extremities. The proximal extremity is called the **base** and the distal extremity, the **head**, in a manner similar to the metacarpal bones. The **body** tapers distally and is convex dorsally, and its sides are marked by rough ridges which give attachment to the fibrous sheaths of the flexor tendons.

The **bases** of the bones of the **proximal row of phalanges** present oval, concave articular surfaces, which are broader from side to side and articulate with the rounded, smooth heads of the metacarpal bones. The **heads** of the proximal row of phalanges are smaller than the bases, and each ends in two condyles separated by a shallow groove. The articular surface extends farther on the palmar than on the dorsal surface.

The bases of each of the bones in the **middle row of phalanges** present two small concave facets separated by an elevated median ridge, allowing them to articulate snugly and conform to the grooved heads of the proximal phalanx. The heads of the phalanges of the middle row are pulley-shaped and end, as do those in the proximal row, in two condyles between which is a groove (Fig. 4-180).

The **distal row of phalanges** are convex on their dorsal and flat on their palmar surfaces, and they can be recognized by their small size. Their bases are identical in shape to those in the middle row, but their distal extremities present a roughened, horse-shoe-shaped elevation on the palmar surface, called the **ungual tuberosity**, which supports the fingernail and the sensitive pulp of the fingertips.

**MUSCLE INSERTIONS.** The edges of the palmar surface of the middle phalangeal bases in the four ulnar fingers receive the insertion of the *flexor digitorum superficialis* tendons. Onto the palmar surface of the distal phalangeal bases are inserted the tendons of the *flexor digitorum profundus*. The *interosseous muscles* insert onto the bases of the proximal phalanges. Onto the medial aspect of the phalangeal base of the little finger insert the *flexor digiti minimi brevis* and the *abductor digiti minimi*. The base of the proximal phalanx of the thumb receives the insertions of the *flexor* and *abductor pollicis brevis* as well as the *adductor pollicis*. The *extensor digitorum* tendons insert onto the dorsal aspect of the bases of the middle and distal phalanges. Onto the dorsum of the base of the middle phalanx of the index finger is inserted the *extensor indicis* tendon. The dorsum of the proximal phalangeal base of the thumb receives the insertion of the *extensor pollicis brevis*, while onto the distal phalanx is inserted the *extensor pollicis longus* (Figs. 4-170; 4-171).

**ARTICULATIONS.** In the four fingers the proximal phalanges articulate with the middle phalanges and with the metacarpals. The middle phalanges articulate with both the proximal and distal phalanges, while the distal phalanges articulate only with the middle. In the thumb, which has only two phalanges, the first phalanx articulates by its base with the metacarpal bone and by its head with the ungual phalanx.

**OSSIFICATION OF THE BONES OF THE HAND.** The **carpal bones** (Figs. 4-178; 4-179) are each ossified from a single center, and although individual variation is observed, ossification generally proceeds in the following order (Fig. 4-177): in the *capitate* and *hamate*, during the first year after birth, the former preceding the latter; in the *triquetral*, during the

FIG. 4-177. Plan of ossification of the hand.

third year; in the *lunate*, during the fourth year in females and the fifth year in males; in the *trapezium*, *trapezoid*, and *scaphoid*, during the fifth year in females and during the sixth and seventh years in males; and in the *pisiform* during the ninth year in females and the eleventh year in males. Ossification is usually bilaterally symmetrical.

The **metacarpal bones** are each ossified from two centers: one for the body and one for the distal extremity (the heads) of each of the second, third, fourth, and fifth bones. One of the two ossification centers of the first metacarpal bone occurs in the body, but in contrast to the other metacarpals, the second ossification center occurs at the base. The first metacarpal bone is therefore ossified in the same manner as the phalanges, and this has led some anatomists to regard the thumb as being made up of three phalanges, and not of a metacarpal bone and two phalanges. Ossification commences in the middle of the body about the eighth or ninth week of fetal life. The centers for the second and third metacarpals are the first to appear, and that for the first metacarpal, the last. At about the third year the distal extremities (heads) of the metacarpals of the fin-

gers and the base of the metacarpal of the thumb begin to ossify. They unite with the bodies between the eighteenth and twentieth year.

The **phalanges** are each ossified from two centers: one for the body and one for the base. Ossification begins in the body of the phalanges at about the eighth week of fetal life. Ossification of the base commences in the proximal phalanges during the second year, and a year later in middle and distal phalanges. The two centers become united in each row before the twentieth year.

In the distal phalanges the centers for the bodies appear at the heads (distal extremity) of the phalanges, instead of at the middle of the bodies, as in other phalanges. Moreover, of all the bones of the hand, the distal phalanges are the first to ossify.

**VARIATIONS.** Occasionally an additional bone, the *os centrale*, is found on the dorsum of the wrist, lying between the scaphoid, trapezoid, and capitate. During the second month of fetal life it is represented by a small cartilaginous nodule, which usually fuses with the cartilaginous scaphoid. Sometimes the **styloid process** of the third metacarpal is detached and forms an additional bone.

**Fig. 4-178.** Hand and wrist of a child aged  $2\frac{1}{2}$  years. The capitate and hamate bones are in process of ossification, but the other carpal bones are still cartilaginous. The center for the head of the ulna has not yet appeared, but the center for the lower epiphysis of the radius is present. Note the condition of the metacarpal bones and phalanges.

## BONES OF THE LOWER LIMB

### HIP BONE

The **hip bone**, also called the innominate bone (Figs. 4-181 to 4-184), is large, flat, and irregularly shaped. Its middle is constricted, and it is expanded both above and below. Articulating with the opposite hip bone anteriorly in the midline, and with the sacrum posteriorly, it forms the greater part of the bony walls of the pelvic cavity. Also, the two hip bones together form the **pelvic girdle** from which extends the skeleton of the lower extremities. Thus, in position, it is interposed between the vertebral column and the femur, thereby connecting the trunk to the lower limb. Each hip bone consists of three parts, the **ilium**, **ischium**, and **pubis**, which are separated from each other by cartilage in young subjects, but are fused in the adult. The union of the three parts takes

place in and around a large cup-shaped articular cavity, the **acetabulum**, which is situated near the middle of the lateral surface of the bone (Fig. 4-181). The **ilium** is the superior, broad, and expanded portion which extends cranialward from the acetabulum. It forms the upper two-fifths of the acetabulum and acts as the weight-bearing part of the bone. The **ischium** is the most inferior and strongest portion. It proceeds downward from the acetabulum and expands into the large **ischial tuberosity**. Curving ventrally, the ischium then forms with the pubis a large aperture, the **obturator foramen**. The **pubis** extends medialward from the acetabulum and articulates in the midline at the **symphysis pubis** with the bone of the opposite side. The anterior aspect of the pubic bones forms the front of the pelvis and supports the overlying external genital organs.

**THE ILIUM.** The **ilium** (Figs. 4-182 to 4-184) is divisible into two parts, the smaller **body**

**Fig. 4-179.** Hand and wrist of a child aged 11 years. All the centers of ossification are present except that for the pisiform bone. Note how the first metacarpal differs from the other metacarpal bones.

and the expanded upper portion called the **ala**. The junction of these two parts is indicated on the internal surface by the **arcuate line** (Fig. 4-183) and on the external surface by the margin of the acetabulum.

The **body** of the ilium enters into the formation of the acetabulum, of which it forms rather less than two-fifths. Its **external surface** (Fig. 4-182) is partly articular, partly nonarticular. The articular segment forms a portion of the **lunate surface** of the acetabulum, i.e., the walls of the acetabular cup. The nonarticular portion contributes to the roughened floor of the cavity, or the **acetabular fossa**. The **internal surface** (Fig. 4-183) of the body is part of the wall of the lesser pelvis and gives origin to some fibers of the obturator internus muscle. It is continuous below with the pelvic surfaces of the ischium and pubis, only a faint line indicating the place of union.

The **ala** or wing is the large expanded portion which bounds the greater pelvis laterally. It presents for examination two surfaces—a gluteal and a sacropelvic, and a

crest, and two borders—an anterior and a posterior.

The **gluteal surface** is oriented laterally and posteriorly behind, and laterally and somewhat inferiorly in front. It is smooth and convex ventrally, but deeply concave dorsally. The gluteal surface is bounded superiorly by the **iliac crest**, inferiorly by the superior border of the acetabulum, and in front and behind by the anterior and posterior borders of the ala. This surface is crossed in an arched direction by three ridges—the posterior, anterior, and inferior gluteal lines. The **posterior gluteal line**, the shortest of the three, begins above on the outer lip of the iliac crest about 5 cm in front of its posterior extremity. The upper part of this line is distinctly marked, but as it passes downward toward its termination at the **greater sciatic notch**, it becomes more obscure and difficult to define (Figs. 4-182; 4-184). Dorsal to this line is a narrow semilunar surface which is rough and gives origin to a small portion of the gluteus maximus. From a smoother region below this origin of

**Fig. 4-180.** Radiograph of the adult wrist and hand. Note the sesamoid bone in the thumb in relation to the metacarpophalangeal joint.

the gluteus maximus attach fibers of the sacrotuberous ligament as well as the iliac head of the piriformis muscle. The **anterior gluteal line** is the longest of the three. It begins at the outer lip of the iliac crest, about

**Fig. 4-181.** The hip bone of a 14-year-old child viewed from the lateral aspect. (From Benninghoff and Goertler, 1975.)

4 cm from its ventral extremity, and taking a curved direction downward and backward, ends at the greater sciatic notch (Figs. 4-182 to 4-184). Near the middle of this line a nutrient foramen is often seen. The space between the anterior and posterior gluteal lines and the iliac crest is concave, and gives origin to the gluteus medius. The **inferior gluteal line**, the least distinct of the three, begins anteriorly at the border of the ilium somewhat above the anterior inferior iliac spine. It curves backward and downward to end near the upper part of the greater sciatic notch. The surface of bone included between the anterior and inferior gluteal lines gives origin to the gluteus minimus. Between the inferior gluteal line and the upper part of the acetabulum is a rough, shallow groove, from which the reflected head of the rectus femoris muscle arises.

The **sacropelvic surface** of the ala is oriented medially and posteriorly toward the pelvis and sacrum. It is the internal surface, and is bounded above by the iliac crest, below by the **arcuate line**, and in front and behind by

FIG. 4-182. Right hip bone. Lateral or external aspect.

the anterior and posterior borders of the ilium (Fig. 4-183). It presents a large, smooth, concave surface, called the **iliac fossa**, from which arises the iliacus muscle and which is perforated at its inner part by a nutrient canal. Behind the iliac fossa is a rough surface, divided into two portions, an anterior and posterior. The anterior part or **auricular surface**, so-called from its resemblance in shape to the ear, is coated with cartilage, and articulates with a similar surface on the side of the sacrum. The posterior portion, known as the **iliac tuberosity**, is elevated and rough, for the attachment of the dorsal sacroiliac ligament and for the origins of the erector

spinae muscle. Anterior and below the auricular surface is the **preauricular sulcus**, better marked in the female than in the male. To this rough groove attach fibers of the ventral sacroiliac ligament.

The **iliac crest** is convex and like an arch in its general outline, but it is sinuously curved. To it attach the broad, flat muscles of the anterior abdominal wall, certain muscles of the lower back, and others of the lower extremity. The crest is thinner at the center than at the extremities, and ends in the **anterior and posterior superior iliac spines**. The surface of the crest is broad; it is divided into **external and internal lips**, and an **intermedi-**

FIG. 4-183. Right hip bone. Medial or internal aspect.

**ate line.** About 5 cm dorsal to the anterior superior iliac spine there is a prominent **tubercle** on the outer lip. To the external lip are attached the fascia lata along with the tensor fasciae lata muscle, the external oblique muscle, and more posteriorly the latissimus dorsi muscle. Along the intermediate line arises the internal oblique, while to the internal lip attach the transversus abdominis, quadratus lumborum, and erector spinae muscles, the lumbodorsal fascia and the iliacus muscle and iliac fascia (Figs. 4-182; 4-183).

The **anterior border** of the ala is concave. It presents two projections, separated by a

notch. Of these, the more cranial, situated at the junction of the crest and ventral border, is called the **anterior superior iliac spine** (Fig. 4-184). Its outer border gives attachment to the fascia lata and the tensor fasciae latae, its inner border to the iliacus; its extremity affords attachment to the inguinal ligament and the origin of the sartorius. To a notch inferior to the spine extends the origin of the sartorius, and across this notch passes the lateral femoral cutaneous nerve. Below this notch is the **anterior inferior iliac spine** (Fig. 4-185), which ends near the anterior lip of the acetabulum. This lower spine gives attachment above to the straight tendon of the

**FIG. 4-184.** Right hip bone with sacrum and coccyx. External or lateral surface. (From Benninghoff and Goertler, 1975.)

**FIG. 4-185.** Roentgenogram of adult pelvis. The upper arrow indicates the line of the sacroiliac joint; the lower arrow points to the anterior inferior iliac spine.

rectus femoris muscle and below to the iliofemoral ligament of the hip joint. Medial to the anterior inferior spine is a broad, shallow groove, over which the iliacus and psoas major muscles pass. This groove is bounded medially by an eminence, the **iliopectineal eminence** (Fig. 4-182), which marks the point of union of the ilium and pubis.

The **posterior border** of the ala is shorter than the anterior and also presents two projections, the **posterior superior iliac spine** and the **posterior inferior iliac spine**, which are separated by a notch. The upper spine serves for the attachment of the oblique portion of the dorsal sacroiliac ligaments and the multifidus. The lower spine corresponds with the dorsal extremity of the auricular surface. Inferior to the posterior inferior spine is the deeply indented **greater sciatic notch**.

**THE ISCHIUM.** The ischium (Figs. 4-182 to 4-184) forms the inferior and posterior part of the hip bone. It is L-shaped, interposed between the ilium above and the pubis in front, and is divided into a **body** and a **ramus**.

The **upper portion** of the **body** of the ischium enters into and constitutes a little more than two-fifths of the acetabulum. Its external surface forms part of the lunate surface of the acetabulum and a portion of the acetabular fossa. The internal surface of the upper part of the ischial body forms a portion of the wall of the lesser pelvis, and gives origin to some fibers of the obturator internus muscle. From the posterior border there extends a thin and pointed triangular eminence, the **ischial spine**, which is more or less elongated in different subjects. The outer surface of the spine gives attachment to the gemellus superior, while to its inner surface attach the coccygeus and levator ani muscles, and the pelvic fascia. The sacrospinous ligament is attached to the pointed extremity of the ischial spine. Superior to the spine is a large notch, the **greater sciatic notch**, which becomes converted into the **greater sciatic foramen** by the sacrospinous ligament. Through this foramen pass a number of structures from within the pelvis into the gluteal region. It transmits the piriformis muscle, the superior and inferior gluteal vessels and nerves, the sciatic and posterior femoral cutaneous nerves, the internal pudendal vessels, the pudendal nerve, and the nerves to the obturator internus and

quadratus femoris muscles. Of these, the superior gluteal vessels and nerve pass out above the piriformis, the other structures below it. Also inferior to the spine is a smaller notch, the **lesser sciatic notch**. It is smooth, coated with cartilage, and presents two or three ridges corresponding to the subdivisions of the tendon of the obturator internus, which glides over it. It is converted into the **lesser sciatic foramen** by the sacro-tuberous and sacrospinous ligaments. Through the foramen course the tendon of the obturator internus, the nerve that supplies that muscle, and the internal pudendal vessels and pudendal nerve. Having emerged from the pelvis through the greater sciatic foramen, the internal pudendal vessels and the pudendal nerve cross over the ischial spine and go through the lesser sciatic foramen to enter the perineum between the obturator internus muscle and its fascia.

The **lower portion** of the **body** of the ischium (formerly called the superior or descending ramus) projects caudally and dorsally from the acetabulum. It presents three surfaces: external, internal, and dorsal. The **external surface** is quadrilateral and, in the articulated hip, faces anterolaterally and inferiorly toward the thigh. It is bounded above by a groove that lodges the tendon of the obturator externus. Below, this surface becomes continuous with the ramus of the ischium. *In front*, it is bounded by the posterior margin of the obturator foramen, while *behind*, a prominent margin separates it from the internal or dorsal surface. Anterior to this margin the external surface gives origin to the quadratus femoris and to some of the fibers of origin of the obturator externus. The lower part of the surface gives origin to part of the adductor magnus. The **internal surface** forms part of the bony wall of the lesser pelvis. *In front*, it is bounded by the posterior margin of the obturator foramen. *Below*, it is bounded by a sharp ridge which gives attachment to the falciform process of the sacrotuberous ligament, and more anteriorly gives origin to the transversus perinei and ischiocavernosus. Posteriorly, a large swelling, the **ischial tuberosity**, is divided into two portions: a lower, rough, somewhat triangular part, and an upper, smooth, quadrilateral portion. The **lower portion** is subdivided by a prominent vertical ridge into two parts: the larger, lateral area gives attachment to the adductor magnus, the medial af-

fords attachment to the sacrotuberous ligament, and supports the body in the sitting position. The upper portion allows attachment of the hamstring muscles. An oblique ridge subdivides this portion into a proximal area, from which the semimembranosus arises, and a distal area for the head of the biceps femoris and the semitendinosus.

The **ramus** of the ischium is the thin, flattened part of the ischium, which ascends from the lower part of the body and joins the inferior ramus of the pubis, the junction being indicated in the adult by a raised line. The combined rami are sometimes called the **ischiopubic ramus**. The ischial ramus presents an **external** (anterior) **surface** oriented anteroinferiorly toward the thigh, and an **internal** (posterior) **surface** oriented posterosuperiorly toward the perineum and pelvis. The external surface is uneven, and gives origin to the obturator externus and some of the fibers of the adductor magnus, while the internal surface forms part of the anterior wall of the pelvis. The **medial border** of the ischial ramus is thick, rough, slightly everted, and, together with the medial border of the opposite ischium, forms the bony rim of the inferior outlet of the pelvis. The border presents an outer and an inner ridge along with an intervening space. The ridges are continuous with similar ones along the inferior ramus of the pubis. To the outer ridge is attached the deep layer of the superficial perineal fascia (fascia of Colles), and to the inner ridge, the inferior fascia of the urogenital diaphragm. If the ridges are traced downward, they are found to join with each other just dorsal to the origin of the transversus perinei profundus muscle. The transversus perinei is attached to the intervening space, and ventral to this, a portion of the crus penis or crus clitoris and the ischiocavernosus muscles are attached. The **lateral border** of the ischial ramus is thin and sharp, and forms part of the medial margin of the obturator foramen.

**THE PUBIS.** The **pubis** forms the anterior part of the hip bone. It articulates with the opposite pubis to form the symphysis pubis. It is divisible into a **body**, a **superior ramus**, and an **inferior ramus** (Fig. 4-182).

The **body** of the pubis forms one-fifth of the acetabulum, contributing by its **external surface** both to the lunate surface and the acetabular fossa. Its **internal surface** enters into the formation of the wall of the lesser

pelvis and gives origin to a portion of the obturator internus.

The **superior ramus** extends inferomedially from the body to the median plane, where it articulates with the superior ramus of the opposite side. It is conveniently described in two portions, a flat, **medial portion** and a narrow, prismoid **lateral portion**.

The **medial portion** of the superior ramus is somewhat quadrilateral and presents for examination two **surfaces**—medial and lateral—and three **borders**—superior, medial, and lateral. The **external surface** is rough and directed inferolaterally, and serves for the origin of certain muscles. The adductor longus muscle arises from the upper and medial angle immediately below the crest. More inferiorly, the obturator externus and the adductor brevis muscles, and the proximal part of the gracilis take origin. The **internal surface** is smooth and forms part of the anterior wall of the pelvis. It gives origin to the levator ani and obturator internus muscles, and gives attachment to the puboprostatic ligaments and to a few muscular fibers prolonged from the bladder. The **superior border** presents a prominent elevation, the **pubic tubercle**, which projects ventrally. To it are attached the inferior crus of the superficial inguinal ring and the inguinal ligament. Passing laterally from the pubic tubercle is a well-defined ridge forming a part of the **pecten pubis** (or pectineal line), which marks the brim of the lesser pelvis. To it are attached a portion of the inguinal falx (the conjoined tendon of the internal oblique and transversus muscles), the lacunar ligament, and the reflected inguinal ligament. Medial to the pubic tubercle is the **pubic crest**, which extends to the medial end of the bone. It affords attachment to the inguinal falx, and to the rectus abdominis and pyramidalis muscles. To the point of junction of the pubic crest with the medial border of the bone, as well as to the symphysis pubis, is attached the superior crus of the superficial inguinal ring. The **medial border** of the superior ramus is articular, participating in the formation of the symphysis pubis. It is oval, and marked by eight or nine transverse ridges, separated by grooves which serve for the attachment of a thin layer of cartilage. The cartilage intervenes between the bone and the interpubic fibrocartilaginous lamina or disc. The **lateral border** presents a sharp margin, the **obturator crest**, which forms

part of the circumference of the obturator foramen and affords attachment to the obturator membrane.

The **lateral portion** of the superior ramus presents three surfaces, superior, inferior, and dorsal. Along the **superior surface** is found the **iliopectineal line**, a continuation of the pecten pubis, or pectineal line, which commences at the pubic tubercle. Ventral to this line, the surface of the bone is triangular in shape, and wider laterally than medially. It is covered by the pectineus muscle. The superior surface is bounded laterally by the **iliopectineal eminence**, which indicates the point of junction of the ilium and pubis, and by a prominent ridge which extends from the acetabular notch to the pubic tubercle. The **inferior surface** forms the superior boundary of the obturator foramen. Laterally, it presents an oblique groove for the passage of the obturator vessels and nerve. Medially, a sharp margin, the **obturator crest**, forms part of the circumference of the obturator foramen and gives attachment to the obturator membrane. The **dorsal surface** is intrapelvic in its orientation. It constitutes part of the ventral boundary of the lesser pelvis, and along this surface arise some fibers of the obturator internus muscle.

The **inferior ramus** of the pubis is thin and flattened (Fig. 4-182). It passes laterally and inferiorly from the medial end of the superior ramus. Becoming narrower as it descends, the inferior ramus of the pubis joins with the ramus of the ischium along the obturator foramen. It has two surfaces, external and internal, and two borders, medial and lateral. The **external surface** is rough, for the origin of muscles—the gracilis along its medial border, a portion of the obturator externus where the inferior ramus enters into the formation of the obturator foramen, and between these two, the adductors brevis and magnus, the former being the more medial. The **internal surface** is smooth, and gives origin to the obturator internus and, close to the medial margin, the sphincter urethrae muscles. The **medial border** is thick, rough, and everted, especially in females. It presents two ridges, separated by an intervening space. The ridges extend downward and are continuous with similar ridges on the ramus of the ischium. To the more external of the two ridges is attached the superficial perineal fascia (Colles' fascia), and to the internal ridge the inferior fascia of

the urogenital diaphragm. The **lateral border** is thin and sharp, forms part of the circumference of the obturator foramen, and gives attachment to the obturator membrane.

The **acetabulum** (Figs. 4-182; 4-184) is a deep, cup-shaped, hemispherical cavity located on the lateral aspect of the hip bone, near its center. It is oriented laterally and anteroinferiorly and is formed superiorly by the ilium, inferolaterally by the ischium, and anterosuperiorly by the pubis. A little less than two-fifths of the acetabulum is contributed by the ilium, a little more than two-fifths by the ischium, and the remaining one-fifth by the pubis. It is bounded by a prominent uneven rim, which is thick and strong superiorly, and serves for the attachment of the acetabular labrum, which contracts the orifice and deepens the surface for articulation. The acetabulum is deficient inferiorly and presents a deep indentation, the **acetabular notch** (Fig. 4-184), which is continuous with a *circular nonarticular depression*, the **acetabular fossa**, at the bottom of the hemispherical cavity. The acetabular fossa is perforated by numerous apertures and lodges a mass of fat. The acetabular notch is converted into a foramen by the transverse acetabular ligament whose fibers blend inseparably with the acetabular labrum. The nutrient vessels and nerves traverse the foramen to enter the joint. The margins of the acetabular notch serve for the attachment of the ligament of the head of the femur. The rest of the acetabulum is formed by a *curved articular surface*, the **lunate surface**, for articulation with the head of the femur.

The **obturator foramen** (Figs. 4-182 to 4-184) is a large, rounded aperture, situated below the acetabulum and between the ischium and pubis. It is limited *above* by the **obturator groove** of the superior pubic ramus, *below* by the ischial ramus, *medially* by the inferior ramus and body of the pubis, and *laterally* by the body of the ischium. The obturator foramen is large and oval in the male and somewhat smaller and more triangular in the female. Covering the foramen and attached to its uneven margin is the fibrous obturator membrane. The membrane completely covers the obturator foramen except superiorly where a deep groove, called the **obturator groove**, allows a communication between the pelvis and the thigh. This communication is converted into

a canal by a specialized part of the obturator membrane, which takes the form of a ligamentous band and attaches to two tubercles. One is the **posterior obturator tubercle**, on the medial border of the ischium, just anterior to the acetabular notch, while the other is the **anterior obturator tubercle**, on the obturator crest of the superior ramus of the pubis. Through the canal the obturator vessels and nerve pass out of the pelvis and into the thigh.

**STRUCTURE.** The thicker parts of the hip bone consist of cancellous bone, enclosed between two layers of compact bone. The thinner parts, such as those at the bottom of the acetabulum and at the center of the iliac fossa, are usually translucent and composed entirely of compact bone.

**OSSIFICATION** (Fig. 4-186). The hip bone is ossified from *three primary centers*, one each for the ilium, ischium, and pubis. The centers appear in the following order: in the *lower part of the ilium*, immediately above the greater sciatic notch, about the eighth or ninth week of fetal life; in the *lower portion of the body of the ischium*, about the third month; in the *superior ramus of the pubis*, between the fourth and fifth months. Additionally, five secondary centers appear: at the crest of the ilium, the anterior inferior spine, the ischial tuberosity, the symphysis

pubis, and the Y-shaped strip in the floor of the acetabulum, called the **triradiate cartilage**. At birth, the three primary centers are quite separate, the crest, the bottom of the acetabulum, the ischial tuberosity, the ramus of the ischium, and the inferior ramus of the pubis being still cartilaginous. In a  $3\frac{1}{2}$ -year-old child the ramus of the ischium and the inferior ramus of the pubis are still connected by cartilage (Fig. 4-187), but by the seventh or eighth year they become almost completely united by bone. About the thirteenth or fourteenth year, the three primary centers have extended their growth into the bottom of the acetabulum, and are there separated from each other by the Y-shaped triradiate cartilage, which now presents traces of ossification, often by two or more centers. One of these, the *os acetabuli*, appears about the age of twelve, between the ilium and pubis, and fuses with them about the age of eighteen. It forms the pubic part of the acetabulum. The ilium and ischium then become joined, and lastly the pubis and ischium, through the intervention of the triradiate portion. At about the age of puberty, ossification takes place in each of the remaining portions, and they join with the rest of the bone between the twentieth and twenty-fifth years. Separate centers are frequently found for the pubic tubercle and the ischial spine, and for the pubic crest.

**ARTICULATIONS.** The hip bone articulates with its fellow of the opposite side, and with the sacrum and femur.

By eight centers { Three primary (Ilium, Ischium, and Pubis)

**Fig. 4-186.** Plan of ossification of the hip bone. The three primary centers unite through a Y-shaped piece about puberty. Epiphyses appear about puberty, and unite about the twenty-fifth year.

## BONY PELVIS

The term **pelvis**, which means a basin, is used here to define the skeletal structure interposed between the movable part of the vertebral column, which it supports, and the lower limbs, upon which it rests. Thus, the principal functions of the bony pelvis are to afford attachment of the large musculature of the trunk and lower limbs, to protect the pelvic viscera, and to withstand the pressures and yet allow the functions of urination, defecation, and parturition. The pelvis is stronger and more massively constructed than the wall of the cranial or thoracic cavities, and is composed of four bones: the two hip bones laterally and ventrally and the sacrum and coccyx dorsally (Figs. 4-188 to 4-192).

The pelvis is divided into the **greater** and the **lesser pelvis** by an oblique plane passing through the promontory of the sacrum posteriorly, the arcuate line of the ilium, pecten pubis (iliopectineal line), and the superior margin of the symphysis pubis. The circumference of this plane is termed the **linea terminalis** or **pelvic brim**.

**FIG. 4-187.** Pelvis of a child aged 3½ years. The epiphysis for the head of the femur is well formed, but the center for the greater trochanter has not yet appeared. The rami of the pubis and ischium are still connected by cartilage and the triradiate cartilage in the acetabulum is wide.

The **greater or false pelvis** is the expanded portion of the cavity situated above and ventral to the pelvic brim. It is bounded on each side by the ala of the ilium. Ventrally it is incomplete, presenting between the anterior borders of the ilia a wide interval, which is occupied in the intact body by the anterior wall of the abdomen. Posteriorly there is a deep notch between the ilium and the base of the sacrum on each side.

The **lesser or true pelvis** is that part of the pelvic cavity which is situated below the

pelvic brim. The lesser pelvis is continuous with the greater pelvis, but its bony walls are more complete. The cavity of the lesser pelvis is of extreme importance in obstetrics, and measurements of its diameters are of clinical significance. The inlet to the cavity of the lesser pelvis is bounded by the superior circumference, and its outlet bounded below by the inferior circumference.

The **superior circumference** is formed by the brim of the pelvis, the enclosed area being called the **superior aperture or inlet**

**FIG. 4-188.** Diameters of superior aperture of lesser pelvis (female). A, Anteroposterior or conjugate diameter. B, Oblique diameter. C, Transverse diameter.

**Fig. 4-189.** Diameters of inferior aperture of lesser pelvis (female). A, Transverse diameters. B, Anteroposterior diameter.

(Fig. 4-188). It is formed laterally by the arcuate line and pecten pubis, anteriorly by the crests of the pubes, and posteriorly by the anterior margin of the base of the sacrum and sacrovertebral angle. The superior aperture is rounded or oval and somewhat heart-shaped. It is obtusely pointed anteriorly, diverges on each side, and is encroached upon dorsally by the projection of the promontory of the sacrum. It has three principal diameters: anteroposterior, transverse, and oblique (Fig. 4-188). The **anteroposterior** or **conjugate diameter** extends from the sacrovertebral angle or promontory to the upper border of the symphysis pubis. Its average measurement is about 11 cm in the female and 10 cm in the male. The **transverse diameter** extends across the greatest width of the superior aperture, from the middle of the brim or iliopectineal line on one side to the same point on the opposite. Its average measurement is about 13.5 cm in the female and 12.5 cm in the male. The **oblique diameter** extends from the sacroiliac joint of one side directly across to the diametrically opposite site on the pelvic brim of the other side (iliopectineal eminence). Its average measurement is about 12.5 cm in the female and 12.0 cm in the male.

The **cavity of the lesser pelvis** (Fig. 4-172) is bounded anteriorly and below by the pubic symphysis and the body and rami of the pubes, posteriorly by the pelvic surfaces of the sacrum and coccyx, and laterally by a broad, smooth, quadrangular area of bone, on the inner surfaces of the bodies of the

ischium and ilium. The cavity of the lesser pelvis is short and curved, being considerably deeper on its posterior than on its anterior wall. In the intact body, it contains the pelvic colon, rectum, bladder, and certain reproductive organs. The rectum courses along the dorsum of the pelvis in the curve of the sacrum and coccyx, while the bladder lies against the dorsal surface of the pubic

**Fig. 4-190.** A median sagittal diagram of the female pelvis showing that the plane of the pelvic inlet forms an angle of 50 to 60 degrees with the horizontal plane, while the plane of the outlet forms an angle of 15 degrees. Observe the curvature of the pelvic axis between the planes of inlet and outlet.

FIG. 4-191. Male pelvis. Anterior aspect.

symphysis. In the female the uterus and vagina occupy the interval between these viscera.

The **inferior circumference** of the pelvis is more irregular than the superior circumference. The outlet enclosed by its perimeter is named the **inferior aperture** (Fig. 4-189). It is bounded dorsally by the sacrum and coccyx, and laterally by the ischial tuberosities. These bony landmarks are separated by three notches, one of which, the **pubic arch**, lies anterior to the tuberosities and is formed

by the convergence of the inferior rami of the pubes. Two dorsal notches, one on each side, extend deeply between the sacrum and the ischium. They are called the **sciatic notches**. In the intact body each sciatic notch is converted into the **greater and lesser sciatic foramina** by the sacrotuberous and sacrospinous ligaments. With the ligaments in position, the inferior aperture of the pelvis is nearly diamond-shaped, bounded anteriorly by the pubic arcuate ligament and the inferior rami of the pubes, *laterally* by

FIG. 4-192. Female pelvis. Anterior aspect.

the ischial tuberosities, and *dorsally* by the sacrotuberous ligaments and the tip of the coccyx.

The two **diameters** of the **outlet** of the **pelvis** are anteroposterior and transverse. The **anteroposterior diameter** extends from the tip of the coccyx to the inferior edge of the symphysis pubis at the midline anteriorly. Its measurement varies between 9 and 11.5 cm in the female (in comparison to 10.5 to 11 cm in the male) because of the varying length of the coccyx. Additionally, its length may be increased or diminished by the mobility of that bone. The **transverse diameter**, measured between the dorsal parts of the ischial tuberosities, is about 11 cm in the female and 9 cm in the male.

**PELVIC AXIS.** The **pelvic axis** is an imaginary curved line passing through the lesser pelvis at right angles to the plane of the superior aperture and inferior aperture at their centers, and all the planes between them (Fig. 4-190). A line at right angles to the plane of the superior aperture at its center would, if prolonged, pass through the umbilicus and the middle of the coccyx and is therefore directed downward and backward. The axis of the inferior aperture, if prolonged, would touch the promontory of the sacrum. Thus, the axis of the pelvic cavity between the superior and inferior apertures is curved like the cavity itself, corresponding to the concavity of the sacrum and coccyx. An appreciation of the direction of these axes is especially relevant to an understanding of the course of the fetus in its passage through the pelvis during parturition.

**POSITION OF THE PELVIS.** In the standing position, the pelvis is so tilted forward that the plane of the superior aperture forms an angle of 50 to 60 degrees with the horizontal plane, and that of the inferior aperture an angle of about 15 degrees (Fig. 4-190). This **inclination of the pelvis** causes the pelvic surfaces of the symphysis pubis to be directed superiorly and posteriorly, while the concavity of the sacrum and coccyx is oriented inferiorly and anteriorly. The position of the pelvis in the erect posture may be indicated by holding it so that the anterior superior iliac spines and the top of the symphysis pubis are in the same plane.

**DIFFERENCES BETWEEN THE MALE AND FEMALE PELVIS.** The morphological differences encountered between the male and female pelvis reflect differences in function. The

reproductive function in the female and the more muscular nature of the male become to some extent manifested in pelvic anatomy. The female pelvis (Fig. 4-192) when compared with that of the male (Fig. 4-191) is more delicate in its bone structure. Because the female pelvis is less massive, its overall size and dimensions are smaller, and its muscular impressions are less marked. The curvature of the ilia is more pronounced in the male in such a manner that its angle of approach to the pubis is more acute and less rounded. Thus, in the female the anterior iliac spines are more widely separated, causing the greater lateral prominence of the hips. The superior aperture of the lesser pelvis in the female is larger than in the male. It is also more nearly circular, and its obliquity is greater. **In the female**, the **true pelvic cavity** is shallower and wider; the sacrum is shorter, wider, and less curved; the **obturator foramina** are more triangular in shape and smaller in size; the **inferior aperture** is larger and the coccyx more movable; the **sciatic notches** are wider and shallower; the **ischial spines** project less; the **acetabula** are smaller and face more ventrally; the **ischial tuberosities** and the **acetabula** are wider apart, and the former are more everted; the **pubic symphysis** is less deep, and the **pubic arch** is wider and more rounded, and its angle less acute (Figs. 4-191; 4-192).

The **size of the pelvis** varies not only in the two sexes, but also in different members of the same sex. Pelvic size does not appear to be influenced by an individual's height, although women of short stature, as a rule, have broad pelves. Occasionally the pelvis is equally contracted in all its dimensions, so that all its diameters measure 1.25 cm less than average, even in otherwise well-formed women of average height. The principal divergences, however, are found in the shape of the superior aperture, affecting the relationship between the anteroposterior and transverse diameters. Thus the superior aperture may be elliptical in either a transverse or an anteroposterior direction. In the former, the transverse diameter, and in the latter, the anteroposterior diameter greatly exceed the other diameters. In other instances the superior aperture is almost circular.

In the fetus, and for several years after birth, the pelvis is smaller in proportion to the body than it is in the adult, and the pro-

jection of the sacrovertebral angle less marked. The characteristic differences between the male and female pelvis are distinctly indicated as early as the fourth month of fetal life, especially in the nature of the pubic arch and subpubic angle.

### THE FEMUR

The **femur** or thigh bone is the longest and strongest bone in the skeleton, and is almost perfectly cylindrical in the greater part of its extent. Each femur articulates proximally with the hip bone at the acetabulum, and distally with the tibia at the knee joint. Thus, in the erect posture the two femora are more widely separated above than at the knees, and by inclining gradually in an oblique manner inferomedially, they bring the knee joint near the line of gravity of the body. The degree of this inclination varies somewhat, and is greater in the female than in the male because of the greater breadth of the pelvis. The femora transmit the weight of the trunk to the tibias, and they are so covered with muscles that only their upper and lower

ends are palpable. Similar to other long bones, the femur presents two extremities separated by a body or shaft.

**PROXIMAL EXTREMITY.** The proximal extremity (Fig. 4-193) consists of a head, a neck, and a greater and a lesser trochanter.

The **head of the femur** is globular, forming rather more than half a sphere. Its surface is smooth and coated with hyaline cartilage, except over an ovoid depression or pit near its center, the **fovea** of the head of the femur, where the ligament of the head of the femur is attached.

The **neck of the femur** is a pyramidal process of bone connecting the femoral head with the body, set at an angle of about 125 degrees in the adult. The angle is wider in infancy, and becomes lessened during growth. By puberty the neck forms a gentle curve from the axis of the body of the bone. Variation in the angular shape of the proximal extremity is observed to be dependent on the development of the pelvis and on stature. Because of the increased width of the pelvis in the female, the neck of the femur forms a less obtuse angle (about 110 to 115

FIG. 4-193. The proximal extremity of right femur. Posterior superior aspect.

degrees) with the shaft than it does in the male. The angle varies considerably in persons of different height. In the long-legged male the femoral shaft is more vertical and the femoral neck is more in line (about 140 degrees). In addition to projecting superiorly and medially, the femoral neck also projects somewhat anteriorly from the body of the femur. The amount of this projection is quite variable, but averages 12 to 14 degrees.

The neck is flattened anteroposteriorly, constricted in the middle, and broader laterally than medially. The vertical diameter of the *lateral half* is increased by the obliquity of the lower edge, which slopes to join the body at the level of the lesser trochanter. The *medial half* is smaller and more cylindrically shaped. The **anterior surface** of the neck is perforated by numerous vascular foramina. Along the line of junction of the anterior surface with the head is a shallow groove, best marked in elderly subjects, which lodges the orbicular or circular fibers of the capsule of the hip joint. The **posterior surface** is smooth, and it is broader and more concave than the anterior. The posterior part of the capsule of the hip joint is attached to the femoral neck about 1 cm above the intertrochanteric crest. The **superior border** is short and thick. It ends laterally at the greater trochanter, and its surface is perforated by large foramina. The **inferior border** is long and more narrow and it curves downward, ending at the lesser trochanter.

The **greater trochanter** (Figs. 4-193 to 4-197) is a large, irregular, quadrilateral projection surmounting the junction between the neck and the shaft. It has two surfaces and four borders. The **lateral surface** is broad, rough, convex, and marked by a diagonal impression for the insertion of the tendon of the gluteus medius muscle. Above this impression is a triangular surface which sometimes is rough for part of the gluteus medius tendon, and at other times smooth for the interposition of a bursa between the tendon and the bone. Below the diagonal impression is a smooth triangular surface, over which the gluteus maximus muscle glides, a bursa being interposed. The **medial surface** of the greater trochanter is less extensive than the lateral surface. At its base is found a deep depression, the **trochanteric fossa**, where the obturator externus inserts, and anterior to this an impression for the insertion of the obturator internus and the

**Fig. 4-194.** The left femur viewed from the anterior aspect. (From Benninghoff and Goerttler, 1975.)

gemelli muscles. The **superior border** is thick and irregular, and marked near the center by an impression for the insertion of the piriformis. The **inferior border** corresponds to the line of junction of the base of the trochanter with the lateral surface of the shaft. It is marked by a rough, prominent, slightly curved ridge, which gives origin to the proximal part of the vastus lateralis. The **anterior border** is prominent and somewhat irregular, and affords insertion at its lateral

**FIG. 4-195.** The left femur viewed from the posterior aspect. (From Benninghoff and Goerttler, 1975.)

part to the gluteus minimus. The **posterior border** is very prominent and appears as a free, rounded edge which bounds the trochanteric fossa.

The **lesser trochanter** (Figs. 4-193 to 4-197) is a conical eminence which projects medially and posteriorly from the base of the neck. Three well-marked **borders** extend from its apex. The medial is continuous with the lower border of the neck, the lateral with the intertrochanteric crest, the inferior with

the middle division of the linea aspera. The summit of the trochanter is roughened for the insertion of the tendon of the psoas major. More inferiorly, the iliacus muscle inserts along the junction of the lesser trochanter with the femoral shaft.

The **intertrochanteric line** (Figs. 4-194; 4-196) courses obliquely from the greater trochanter to the lesser on the anterior surface of the proximal extremity. This ridge commences with a tubercle of variable size at the junction of the greater trochanter and the distal part of the neck of the femur. The intertrochanteric line, forming the junction of the neck with the femoral shaft on the anterior surface, winds beyond the lesser trochanter and ends about 5 cm below this eminence in the linea aspera. Its proximal half is rough and affords attachment to the iliofemoral ligament, while its lower half, which is less prominent, gives origin to the proximal part of the vastus medialis.

The **intertrochanteric crest** (Figs. 4-195; 4-197) is a prominent ridge along the posterior surface of the proximal extremity extending in an oblique curve from the summit of the greater trochanter to the lesser. It marks the junction between the neck and the shaft posteriorly. Slightly above its middle is an elevation called the **quadratus tubercle**, which receives the insertion of the quadratus femoris and a few fibers of origin of the adductor magnus.

**BODY OR SHAFT.** The **body or shaft** is almost cylindrical, but a little broader proximally than in the center and broadest and somewhat flattened distally (Figs. 4-194 to 4-197). It is slightly arched, convex anteriorly and concave posteriorly, where it is strengthened by a prominent longitudinal ridge, the **linea aspera**. It has three **borders**—posterior, lateral, and medial, and four **surfaces**—popliteal, anterior, lateral, and medial.

The **linea aspera** (Fig. 4-195), which forms the prominent **posterior border** of the shaft, projects as an elevated longitudinal ridge or crest along the posterior aspect of the middle third of the bone. This crest consists of a **medial** and a **lateral lip**, and a narrow, rough, intervening band. The **linea aspera** is *prolonged proximally* by three ridges. The **lateral ridge** is very rough and courses almost vertically upward to the base of the greater trochanter. It is termed the **gluteal tuberosity**, and gives attachment to the gluteus max-

imus. The proximal part of the gluteal tuberosity is often elongated into a rough crest, on which a more or less well-marked, rounded tubercle, the **third trochanter**, is occasionally developed. The *intermediate ridge* or **pectineal line** is continued to the base of the lesser trochanter and gives attachment to the pectineus muscle. The *medial ridge* winds anteriorly to the intertrochanteric line distal to the area where the iliacus muscle is inserted. The *linea aspera* is prolonged distally into two ridges, enclosing between them a triangular area, the **popliteal surface**, which forms the floor of the upper part of the popliteal fossa. Of the two descending ridges, the *lateral ridge* is more prominent, extending to the summit of the lateral condyle. The *medial ridge* is less marked, especially at its proximal part, where it is crossed by the femoral artery. This ridge ends distally at the summit of the medial condyle as the **adductor tubercle**, which receives the insertion of the tendon of the adductor magnus muscle.

The **medial lip of the linea aspera** and its prolongations proximally and distally give origin to the vastus medialis, while from the **lateral lip** and its proximal prolongation arises the vastus lateralis (Fig. 4-197). The adductor magnus is inserted into the linea aspera, and into its lateral prolongation proximally, and its medial prolongation distally. Between the vastus lateralis and the adductor magnus, two muscles are attached, the gluteus maximus above, and the short head of the biceps femoris below. Between the adductor magnus and the vastus medialis four muscles are inserted: the iliacus and pectineus proximally, and the adductor brevis and adductor longus distally. The linea aspera is perforated a little below its center by the **nutrient canal**, which is directed obliquely upward.

The other two borders of the femur are only slightly marked. The **lateral border** extends from the anteroinferior angle of the greater trochanter to the anterior extremity of the lateral condyle, and the **medial border** stretches from the intertrochanteric line, at a point opposite the lesser trochanter, to the anterior extremity of the medial condyle.

The **anterior surface**, which lies between the lateral and medial borders, is smooth, rounded, and convex. The vastus intermedius arises from the upper three-quarters of the anterior surface. The lower one-quarter of the bony surface is separated from the

muscle by the intervention of the synovial membrane from the knee joint and by the suprapatellar bursa. Above the bursa arises the articularis genu muscle. The **lateral surface** extends between the lateral border and the linea aspera and is continuous with the corresponding surface of the greater trochanter proximally, and with that of the lateral condyle distally. The vastus intermedius takes origin from its proximal three-fourths. The **medial surface** is smooth like the anterior and lateral surfaces, and stretches between the medial border and the linea aspera. This surface is continuous with the distal border of the neck proximally, and with the medial side of the medial condyle distally. No muscles attach to the medial surface, but it is covered by the vastus medialis.

**DISTAL EXTREMITY.** The distal extremity of the femur (Figs. 4-194 to 4-198) is greatly expanded in all directions to form two prominences, the **medial** and **lateral condyles**, which are joined together anteriorly but separated posteriorly by the **intercondylar fossa** or **notch** (Fig. 4-198). The distal surface is coated with hyaline cartilage for articulation with the tibia. The articular surface of the lateral condyle is longer and narrower than that of the medial condyle. Both condyles are nearly flat anteroposteriorly, but greatly curved on their posterior surface.

The **medial condyle** diverges more from the anteroposterior plane and projects somewhat farther distally than the **lateral condyle** when the femoral shaft is held perpendicularly. When, however, the femur is in its natural oblique position, the two condyles lie practically in the same horizontal plane. At the junction of the articular surfaces of the two condyles anteriorly, there is a shallow depression, the **patellar surface**. Between the condyles posteriorly is a deep notch, the **intercondylar fossa**. The walls of the fossa are rough and concave, and the fossa is limited proximally by the **intercondylar line** and distally by the margin of the patellar surface. The posterior cruciate ligament of the knee joint is attached to the anterior part of the lateral surface of the medial condyle, which forms the medial wall of the fossa. This ligament also extends to the floor of the fossa. The anterior cruciate ligament is attached to an impression on the proximal and posterior part of the lateral wall of the fossa, formed by the medial surface of the lateral condyle.

**Fig. 4-198.** Lower extremity of right femur viewed from below.

The **epicondyles** are two roughened convex prominences which surmount the condyles proximally. The **medial epicondyle** receives the attachment of the tibial collateral ligament of the knee joint. At the upper part of the medial epicondyle is the **adductor tubercle** (Figs. 4-196; 4-197) for the insertion of the adductor magnus, and posterior to this, the medial head of the gastrocnemius takes origin. The **lateral epicondyle**, smaller and less prominent than the medial, gives attachment to the fibular collateral ligament of the knee joint. Directly below the lateral epicondyle is a small depression from which a smooth well-marked groove curves upward and backward to the posterior extremity of the condyle. This groove is separated from the articular surface of the condyle by a prominent lip across which a second, shallower groove runs vertically from the depression. In the intact body these grooves are covered with cartilage. The popliteus muscle arises from the depression, and its tendon lies in the oblique groove when the knee is flexed and in the vertical groove when the knee is extended. Above and posterior to the lateral epicondyle is an area for the origin of the lateral head of the gastrocnemius, and above this arises the plantaris muscle.

The **articular surface** of the distal end of the femur occupies the anterior, distal, and posterior surfaces of the condyles. Its anterior part, the **patellar surface**, articulates with the patella. This surface presents a median groove which extends toward the intercondylar fossa, and two convexities, the lateral of which is broader, more prominent, and extends farther proximally than the medial. The distal and more posterior parts

of the articular surface constitute the **tibial surfaces** for articulation with the corresponding condyles of the tibia and menisci. These surfaces are separated from the patellar surface by faint grooves which extend obliquely across the condyles (Fig. 4-198). The **lateral groove** is the better marked and can be seen coursing laterally and anteriorly from the intercondylar fossa, and expanding to form a triangular depression. When the knee joint is fully extended, the triangular depression rests upon the anterior portion of the lateral meniscus. The medial part of the lateral groove comes into contact with the medial margin of the lateral articular surface of the tibia, anterior to the lateral tubercle of the tibial intercondylar eminence. The **medial groove** is less distinct than the lateral. It does not reach as far as the intercondylar fossa, and therefore exists only on the medial part of the condyle. It receives the anterior edge of the medial meniscus when the knee joint is extended. Where the medial groove ceases laterally is seen a **semilunar area** which is a posterior continuation of the patellar surface close to the anterior part of the intercondylar fossa (Fig. 4-198). This semilunar area articulates with the medial vertical facet of the patella in forced flexion of the knee joint. The tibial surfaces of the condyles are convex both from side to side and anteroposteriorly. The anteroposterior length of the tibial surface of the medial condyle is slightly greater than that of the lateral condyle.

**ARCHITECTURE.** The femur obeys the mechanical laws that govern other elastic bodies under stress (Koch, 1917). Computations have been made of the stress sustained internally in different parts of the

femur relative to the load placed on the femoral head. It has been found that the internal structure of the different portions of the femur is in very close agreement with the theoretical relations that should exist between stress and structure for maximum economy and efficiency (Figs. 4-199; 4-200).

The spongy bone at the *proximal end of the femur* is composed of two distinct systems of trabeculae arranged in curved paths. One system, called the **compressive system**, has its origin on the medial side of the shaft, and its trabeculae curve upward in a fan-like radiation to the opposite side of the bone. The other, called the **tensile system**, having origin on the lateral portion of the shaft, arches upward and medially to end in the upper surface of the greater trochanter, neck, and head. The trabeculae of these two systems intersect each other at right angles. The trabeculae of the compressive and tensile systems lie exactly in the paths of the maximum tensile and compressive stresses exerted on the femur. The thickness and spacing of the trabeculae vary with the intensity of the maximum stresses at various points, being thickest and most closely spaced in the regions where the greatest stresses occur. The amount of bony material in the spongy bone varies in proportion to the intensity of the shearing force at the various sections. The arrangement of the trabeculae in the positions of maximum stresses is such that the greatest strength is secured with a minimum of bony material.

*In the shaft* the shearing stresses are at a minimum. Very little if any material is in the central space, as practically the only material near the neutral plane is in the compact bone. The hollow shaft of the femur is an efficient structure for resisting **bending stresses**, because all of the material in the shaft is at a considerable distance relative to the neutral axis. It provides resistance to bending movement caused by the load on the femoral head as well as by any other loads tending to produce bending in other planes. The structure of the shaft is such that great strength exists in a relatively small amount of material.

In the distal extremity of the femur there are two main systems of trabeculae, a **longitudinal** and a **transverse system**. The longitudinal trabeculae arise from the inner wall of the shaft and continue in straight parallel lines to the epiphyseal line. They then continue in slightly curved lines to meet the articular surface of the femur at the knee joint at right angles. The transverse trabeculae are lighter in structure and are braced at right angles to the longitudinal trabeculae. Thus, with practically no increase in the amount of bony material used, there is a greatly increased stability produced by the expansion of the lower femur from a hollow shaft of compact bone to a structure of much larger cross-section composed almost entirely of spongy bone.

**OSSIFICATION.** (Figs. 4-201 to 4-203). The femur is ossified from five centers: one each for the

**Fig. 4-199.** Frontal longitudinal midsection of the upper femur; natural size.

**FIG. 4-200.** Frontal longitudinal midsection of a right femur;  $\frac{4}{9}$ th natural size. (From Koch.)

**FIG. 4-201.** Plan of ossification of the femur. From five centers.

body, the head, the greater trochanter, the lesser trochanter, and the distal extremity. Of all the long bones, except the clavicle, the femur is the first to show traces of ossification. This commences in the *middle of the body*, at about the seventh week of fetal life, and rapidly extends proximally and distally. The centers in the epiphyses appear in the following order: in the *distal end of the bone*, at the ninth month of fetal life (from this center the condyles and epicondyles are formed); in the *head*, at the end of the first year after birth; in the *greater trochanter*, during the fourth year; and in the *lesser trochanter*, between the thirteenth and fourteenth years. The order in which the epiphyses are joined to the body is the reverse of that of their appearance. They are not united until after puberty, and the lesser trochanter is the first to join, then the greater trochanter, then the head, and finally the distal extremity, which is not united until the twentieth year.

#### THE PATELLA

The **patella**, commonly called the knee cap (Figs. 4-204; 4-205), is a flat, smooth, triangular bone, situated on the front of the knee joint and embedded on the deep aspect of the tendon of the quadriceps femoris. It is the largest of the sesamoid bones, resembling them by (1) being developed in a ten-

**Fig. 4-202.** Epiphyseal lines of femur in a young adult. Anterior aspect. The lines of attachment of the articular capsules are in blue.

don; (2) presenting a knotty, tuberculated appearance as a result of its ossification; and (3) being composed mainly of dense cancellous tissue. Measuring about 5 cm in diameter, it serves to protect the front of the knee joint and increases the leverage of the quadriceps femoris by making it act at a greater angle. It has an anterior and a posterior surface, three borders, and a pointed **apex** that is directed inferiorly. The lower limit of the apex lies about 1 cm above the level of the knee joint in the erect lower extremity.

The **anterior surface** (Fig. 4-204) is convex,

**Fig. 4-204.** Right patella. Anterior surface.

**Fig. 4-203.** Epiphyseal lines of femur in a young adult. Posterior aspect. The lines of attachment of the articular capsules are in blue.

perforated by small apertures for the passage of nutrient vessels, and marked by numerous rough, longitudinal striae. This surface is covered, in the intact body, by an expansion from the tendon of the quadriceps femoris which is continuous distally with the superficial fibers of the ligamentum patellae. It is easily palpable and separated from the integument by a bursa. The **posterior surface** (Fig. 4-205) presents a smooth, oval, **articular area** covered with cartilage, and divided into two facets by a vertical ridge. This ridge lies adjacent to the groove

**Fig. 4-205.** Right patella. Posterior (articular) surface.

on the anterior surface of the femur, and the facets of the patella articulate with the medial and lateral aspects of the groove. The lateral patellar facet is broader and deeper than the medial. Distal to the articular surface is a rough, convex, nonarticular area, the distal half of which gives attachment to the ligamentum patellae. The proximal half of the nonarticular area is separated from the head of the tibia by adipose tissue.

The **base** or **superior border** is thick and sloped from behind downward and forward. It gives attachment to the portion of the quadriceps femoris muscle that is derived from the rectus femoris and vastus intermedius muscles. The **medial** and **lateral borders** are thinner and converge distally. They give attachment to those portions of the quadriceps femoris that are derived from the vasti lateralis and medialis.

The **apex** is bluntly pointed and gives attachment to the ligamentum patellae, which is a continuation of the quadriceps tendon. The ligamentum patellae, in turn, attaches to the tibia.

**STRUCTURE.** The patella consists of nearly uniform dense cancellous bone, covered by a thin compact lamina. The trabeculae immediately beneath the anterior surface are arranged parallel with it. In the remainder of the bone, the trabeculae radiate from the articular surface toward the other parts of the bone.

**OSSIFICATION.** The patella ossifies from several centers, which usually make their appearance during the second or third year, but may be delayed until the sixth year. These centers then fuse, and ossification is usually completed by puberty or adolescence (Fig. 4-210).

**ARTICULATION.** The posterior surface of the patella actually articulates with the femur, and its tendon, the ligamentum patellae, attaches to the tibia.

## THE TIBIA

The **tibia** (Figs. 4-206 to 4-209) or shin bone is situated at the medial side of the leg and, except for the femur, is the longest bone of the skeleton. It lies nearly parallel to the fibula, and it alone transmits the weight of the trunk and thigh to the foot. The tibia is expanded proximally where it enters into the formation of the knee joint. The shaft again enlarges distally, although to a lesser extent, and ends in an inferior projection, the medial malleolus, which extends beyond the rest of the bone. The tibia presents a body or shaft and two extremities.

FIG. 4-206. Proximal surface of right tibia.

**PROXIMAL EXTREMITY.** The proximal extremity is expanded to form two eminences, the **medial** and **lateral condyles**. The superior **articular surface** presents two smooth articular facets (Figs. 4-206; 4-211). The medial facet is oval and slightly concave. The lateral facet, nearly circular, is concave from side to side, but slightly convex anteroposteriorly, especially where it extends over the posterior surface for a short distance. The central portions of these facets articulate with the condyles of the femur, while their peripheral portions support the menisci of the knee joint, which here intervene between the two bones (Fig. 4-207). Between the articular facets, but nearer the posterior than the anterior aspect of the bone, is a prominent spine, the **intercondylar eminence**. This eminence is surmounted on each side by the **medial** and **lateral intercondylar**

FIG. 4-207. An outline of Figure 4-206 showing the attachment of the menisci and cruciate ligaments.

FIG. 4-208. Bones of the right leg. Anterior surface. Articular capsules outlined in blue.

FIG. 4-209. Bones of the right leg. Posterior surface.

**FIG. 4-210.** Knee of a boy aged 16 years. Lateral view. Note that the upper epiphysis of the tibia includes the tibial tuberosity, which is indicated by the arrow.

**FIG. 4-211.** Adult knee. The gap between the lateral condyles of the femur and tibia is occupied by the articular cartilage of the two bones and the lateral semilunar cartilage.

tubercles onto the sides of which the articular facets are prolonged. Anterior and posterior to the intercondylar eminence are roughened areas for the attachment of the anterior and posterior cruciate ligaments and the menisci. These sites are called the **anterior** and **posterior intercondylar areas**, and they intervene between the medial and lateral condyles (Figs. 4-206; 4-207).

The anterior surface of the proximal extremity of the bone is a flattened triangular area (Fig. 4-208). It is perforated by large vascular foramina and presents a broad oblong elevation, the **tuberosity of the tibia**, which gives attachment to the ligamentum patellae. The tuberosity is divisible into a rounded, smooth proximal portion and a roughened distal portion into which the ligament actually inserts. A bursa intervenes between the deep surface of the ligament and the part of the bone immediately proximal to the tuberosity.

The **medial condyle** presents a deep transverse groove posteriorly for the insertion of the tendon of the semimembranosus (Fig.

**FIG. 4-212.** Knee of a child aged 7½ years. Note that the apex of the head of the fibula and the tubercles of the intercondylar eminence of the tibia are still cartilaginous and therefore cannot be recognized.

4-209). Its medial surface is convex and rough, and gives attachment to the tibial collateral ligament. The **lateral condyle** presents a flat, nearly circular, articular facet posteriorly, for articulation with the head of the fibula (Fig. 4-209). A rough eminence is situated on a level with the proximal border of the tuberosity at the junction of its anterior and lateral surfaces for the attachment of the iliotibial band. Just distal to this, a part of the extensor digitorum longus takes origin and a slip from the tendon of the biceps femoris is inserted.

**BODY OR SHAFT.** The **body** or **shaft** of the tibia is triangular in cross-section and considerably expanded proximally. It gradually tapers from the condyles downward to a point about two-thirds along the shaft, where it is thinnest. It then gradually widens again. The shaft presents medial, lateral, and posterior surfaces, which are separated by anterior, medial, and interosseous borders.

The **anterior border** (Fig. 4-208) is the most prominent of the three borders, and is situated subcutaneously throughout its length. This border is referred to as the "skin," and it commences proximally at the tibial tuberosity and ends distally at the anterior margin of the medial malleolus. It is sinuous and more prominent in the proximal two-thirds of its extent, but becomes smoother and rounded distally. It gives attachment to the deep fascia of the leg.

The **medial border** is smooth and rounded both proximally and distally, but sharp and more prominent in the center. It begins below the posterior part of the medial condyle, and ends at the posterior border of the medial malleolus. Its proximal part for about 5 cm gives attachment to the tibial collateral ligament of the knee joint, and below this insert some fibers of the popliteus muscle. From the middle third of this border arise fibers of the soleus and flexor digitorum longus muscles.

The **interosseous** or **lateral border** is thin and prominent, especially its central part, and gives attachment to the interosseous membrane. It commences just below the fibular articular facet of the lateral condyle and bifurcates distally to form the boundaries of a triangular rough surface for the attachment of the interosseous ligament connecting the tibia and fibula. Thus, the interosseous border extends inferiorly to the inferior tibiofibular joint.

The **medial surface** (Fig. 4-208) is smooth, convex, and broad, and is bounded in front by the anterior border and behind by the medial border. Its proximal third, directed anteriorly and medially, is covered by the aponeurosis derived from the tendon of the sartorius, and by the tendons of the gracilis and semitendinosus muscles, all of which are inserted nearly as far anteriorly as the anterior border. The remainder of this surface lies immediately beneath the skin and superficial fascia and bears no muscular attachments.

The **lateral surface** (Fig. 4-208) is somewhat narrower than the medial and lies between the anterior and interosseous borders. Its proximal two-thirds present a shallow concavity for the origin of the tibialis anterior. Its distal third is smooth and convex and curves gradually forward to the anterior aspect of the bone. Although this lower part of the lateral surface has no muscular attachments, it is crossed by the tendons of the tibialis anterior, extensor hallucis longus, and extensor digitorum longus muscles, arranged in this order from medial to lateral. Between the latter two tendons course the anterior tibial vessels and nerve.

The **posterior surface** (Fig. 4-209) at its proximal part presents a prominent ridge, the **soleal line**, which extends obliquely downward from the posterior part of the articular facet for the fibula to the medial border. It marks the distal limit of the insertion of the popliteus, serves for the attachment of the fascia covering this muscle, and gives origin to part of the soleus, flexor digitorum longus, and tibialis posterior muscles. The triangular area proximal to this line receives the insertion of the popliteus. The middle third of the posterior surface presents a **vertical line**, which commences at the soleal line and is well marked proximally and less distinct distally. It separates the origins of the flexor digitorum longus medially and the tibialis posterior laterally (Fig. 4-209). The remaining part of the posterior surface is smooth and covered by the tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles. Immediately distal to the soleal line is an obliquely directed vascular groove which leads to a rather large **nutrient foramen**.

**DISTAL EXTREMITY.** The distal extremity is less massive than the proximal, and it presents five surfaces: inferior, anterior, poste-

rior, lateral, and medial. On its medial side there projects distally a strong process, the medial malleolus.

The **inferior surface** is quadrilateral and smooth for articulation with the talus. It is concave anteroposteriorly, broader in front than behind, and medially it is continuous with the articular surface of the medial malleolus.

The **anterior surface** of the distal extremity of the tibia is smooth, rounded proximally, and covered by the tendons of the extensor muscles. Distally the anterior surface extends beyond and slightly overhangs the inferior surface, and its distal margin presents a rough transverse depression for the attachment of the articular capsule of the ankle joint.

The **posterior surface** is traversed by a shallow, longitudinal groove that is directed obliquely downward and medially. It is continuous with a similar groove on the posterior surface of the talus and serves for the passage of the tendon of the flexor hallucis longus.

The **lateral surface** of the distal tibial extremity is triangular and presents the **fibular notch**, which serves for articulation with the distal end of the fibula. The upper circumference of the notch is somewhat roughened for the attachment of the interosseous ligament, which connects the two bones. The lateral surface is bounded by two prominent borders continuous above with the interosseous border. They afford attachment to the anterior and posterior ligaments of the lateral malleolus.

The **medial surface** is prolonged distally to form a short pyramid-shaped process, the **medial malleolus**. The medial surface of this process is convex and immediately subcutaneous. Its lateral or articular surface is smooth, slightly concave, and articulates with the talus. The anterior border of the medial malleolus is rough, for the attachment of the anterior fibers of the deltoid ligament of the ankle joint, while its posterior border presents a broad groove, the **malleolar sulcus**, which occasionally is double and lodges the tendons of the tibialis posterior and flexor digitorum longus. The summit of the medial malleolus is marked by a rough depression for the attachment of the deltoid ligament.

**STRUCTURE.** The structure of the tibia is like that of other long bones. The compact wall of the body is

thickest at the junction of the middle and lower thirds of the bone.

**OSSIFICATION.** The tibia is ossified from three centers: one for the body and one for each extremity (Figs. 4-213; 4-214). Ossification begins in the center of the shaft at about the seventh week of fetal life, and gradually extends toward the extremities. The center for the upper epiphysis appears before or shortly after birth. It is flat in form (Fig. 4-212) and has a thin tongue-shaped process in front which forms the tuberosity (Fig. 4-214). The center for the lower epiphysis appears in the second year, and the lower epiphysis joins the shaft at about the eighteenth year, while the upper epiphysis joins the shaft at about the twentieth year. Two additional centers occasionally exist, one for the tongue-shaped process of the upper epiphysis, which forms the smooth part of the tibial tuberosity, and one for the medial malleolus.

### THE FIBULA

The **fibula** (Figs. 4-208; 4-209) is situated on the lateral aspect of the leg and articulates with the tibia proximally and the tibia and talus distally. In proportion to its length, the fibula is the most slender of all the long bones. Because the fibula does not participate in the formation of the knee joint, it is not a weight-bearing bone. It does, however, afford attachment to numerous muscles which tend to twist its shape, and it does participate importantly in the structure of

**Fig. 4-213.** Plan of ossification of the tibia. From three centers.

**FIG. 4-214.** Epiphyseal lines of tibia and fibula in a young adult are shown in black. Lines of attachment of the articular capsules are shown in blue. Anterior aspect.

the ankle joint. Placed parallel to the tibia, the fibula has two extremities and a shaft or body. Its proximal extremity is called the **head of the fibula**, and it is placed slightly posterior to the head of the tibia, below the level of the knee joint. Its distal extremity inclines a little anteriorly and projects beyond the tibia, forming the lateral part of the ankle joint. It projects laterally as the **lateral malleolus**.

**THE HEAD.** The head of the fibula (Figs. 4-208; 4-209) is irregular in form and presents a flattened surface, directed upward, forward, and medially, for articulation with a corresponding surface on the lateral condyle of the tibia. On the lateral side is a thick and rough prominence continued posteriorly into a pointed eminence, the **apex of the head** (styloid process). This gives attachment to the tendon of the biceps femoris muscle and to the fibular collateral ligament of the knee joint, the ligament dividing the tendon into two parts. The remaining part of the circumference of the head is rough, for the attachment of muscles and ligaments. Anteriorly, the head of the fibula presents a tubercle for the origin of the proximal fibers of the peroneus longus and extensor digi-

torum longus muscles (Fig. 4-208), as well as a surface for the attachment of the anterior ligament of the head. Posteriorly, another tubercle gives attachment to the posterior ligament of the head and the origin of the proximal fibers of the soleus muscle (Fig. 4-209).

The slightly narrowed region just below the head of the fibula is sometimes referred to as the **neck of the fibula**. As the common peroneal nerve leaves the popliteal fossa, it courses around the lateral surface of the fibular neck to achieve the anterior aspect of the leg. At this site the nerve lies in a vulnerable position superficially beneath the skin and adjacent to bone.

**BODY OR SHAFT.** The long, narrow shaft of the fibula is almost entirely surrounded by muscles. It presents three borders—*anterior, interosseous, and posterior*, and three surfaces—*medial, posterior, and lateral*.

The **anterior border** (Fig. 4-215) begins proximally in front of the fibular head. It courses distally to a point just below the middle of the bone, where it curves somewhat laterally and bifurcates to embrace a triangular subcutaneous surface immediately above the lateral malleolus. This border gives attachment to an intermuscular septum, which separates the extensor muscles on the anterior aspect of the leg from the peroneus longus and peroneus brevis on the lateral aspect.

The **interosseous border** (Fig. 4-215) is situated on the medial side of the anterior border and runs nearly parallel with it in the proximal third of the fibula, but diverges from it in the distal two-thirds. It begins just below the head of the fibula and ends at the apex of a rough triangular surface immedi-

**FIG. 4-215.** A transverse section through the right tibia and fibula, showing the attachment of the crural interosseous membrane. Viewed from above.

ately proximal to the articular facet of the lateral malleolus (Fig. 4-216). The interosseous border serves for the attachment of the interosseous membrane, which separates the extensor muscles anteriorly from the flexor muscles posteriorly.

The **posterior border** (Fig. 4-215) begins at the apex of the fibula and ends in the posterior aspect of the lateral malleolus. It gives attachment to an aponeurosis which separates the peroneal muscles on the lateral surface from the flexors on the posterior surface.

The **medial surface** is the interval between the anterior and interosseous borders. It is extremely narrow and flat in the proximal third of its extent, but broader and grooved longitudinally in its distal third. It serves for the origin of three muscles: the extensor digitorum longus, extensor hallucis longus, and peroneus tertius (Fig. 4-209).

The **posterior surface** of the fibula is the space between the posterior and interosseous borders. Its proximal three-fourths are separated into posteromedial and posterolateral portions by a longitudinal ridge, the **medial crest** (Fig. 4-215). This crest begins on the medial side of the fibular head and ends by becoming continuous with the interosse-

ous crest at the distal one-fourth of the bone. The medial crest gives attachment to an aponeurosis which separates the tibialis posterior from the soleus and flexor hallucis longus muscles. Thus, the **posterolateral portion** of the posterior surface is included between the posterior border and the medial crest. This portion is continuous distally with the triangular area proximal to the articular surface of the lateral malleolus. Its proximal third is rough, for the origin of the soleus; its distal part presents a triangular surface connected to the tibia by a strong interosseous ligament; the intervening part of the surface is covered by the fibers of origin of the flexor hallucis longus. Near the middle of this surface is the **nutrient foramen**. The **posteromedial portion** is the interval included between the interosseous border and the medial crest. It is grooved for the origin of the tibialis posterior.

The **lateral surface** is the space between the anterior and posterior borders. It is broad, often deeply grooved, and gives origin to the peroneus longus and peroneus brevis.

**LATERAL MALLEOLUS.** The lateral malleolus (Figs. 4-216; 4-217) is the expanded distal portion of the fibula, an enlargement not unlike the head. Its point is less narrow and tapered than the apex, however, and its articular surface broader and more oval in shape with a deep longitudinally running groove, the **lateral malleolar fossa**, beside it. The lateral malleolus is more prominent and descends farther distally than does the medial malleolus on the distal extremity of the tibia (Fig. 4-217). The **lateral surface** is convex, subcutaneous, and continuous with the triangular, subcutaneous surface on the lateral side of the fibular body. The **medial surface** (Fig. 4-216) presents a smooth oval facet anteriorly which articulates with a corresponding surface on the lateral side of the talus. Posterior to this **malleolar articular surface** is a rough depression, which gives attachment to the posterior talofibular ligament. The **anterior border** is thick and rough, and marked by a depression for the attachment of the anterior talofibular ligament. The **posterior border** is broad and presents the shallow malleolar sulcus for the passage of the tendons of the peroneus longus and brevis (Fig. 4-209). The inferior tip is rounded and gives attachment to the calcaneofibular ligament.

**Fig. 4-216.** Distal extremity of right fibula. Medial aspect.

**FIG. 4-217.** Ankle of a child aged 10 years. Note that the inferior epiphyseal line of the fibula is opposite the ankle joint.

**OSSIFICATION.** The fibula is ossified from three centers: one for the shaft and one for each end (Fig. 4-218). Ossification begins in the shaft about the eighth week of fetal life, and extends toward the extremities. At birth the ends are cartilaginous. Ossification commences in the distal end in the second year, and in the proximal about the third or fourth year. The distal epiphysis, the first to ossify, unites with the body about the twentieth year; the proximal epiphysis, about the twenty-fifth year.

### The Foot

Because the bones of the foot must bear the weight of the body as well as transmit thrust in locomotion, it is important that they be structured to lend maximal resilience and elasticity. This is accomplished by their arched arrangement. Each foot forms a half dome with its medial side arched high and the lateral side flattened. Not only transverse, but longitudinal arches as well, contribute to the stability of the foot, and to its ability to withstand shock and distribute weight. The skeleton of the foot (Figs. 4-219; 4-220) consists of three parts: tarsus, metatarsus, and phalanges.

**FIG. 4-218.** Plan of ossification of the fibula. From three centers.

### THE TARSUS

There are seven **tarsal bones**: the talus, calcaneus, cuboid, navicular, and three cuneiforms.

**THE TALUS.** The talus (Figs. 4-221 to 4-224) is the second largest of the tarsal bones and it occupies the proximal part of the tarsus. It supports the tibia, rests upon the calcaneus, and articulates on each side with the malleoli. Distally it articulates with the navicular. The talus consists of a body, a neck, and a head.

The **body** of the talus is cuboidal in shape. Its **superior** or **proximal portion**, the **trochlea**, is convex and covered by a smooth articular surface, which forms a large arc for articulation with the tibia (Figs. 4-221; 4-223). Its lateral surface articulates with the lateral malleolus of the fibula, and its medial with the medial malleolus of the tibia.

Inferiorly, the body of the talus presents two articular areas, the **posterior** and **middle calcaneal surfaces**, separated by a deep groove, the **sulcus tali** (Figs. 4-222; 4-224). In the articulated foot it lies above a similar groove upon the proximal surface of the calcaneus, and forms the **tarsal sinus**, occupied by the interosseous talocalcaneal ligament. The posterior calcaneal articular surface

FIG. 4-219. Bones of the right foot. Dorsal surface.

FIG. 4-220. Bones of the right foot. Plantar surface.

FIG. 4-221. Left talus. Proximal aspect.

(Figs. 4-222; 4-224) is large and oblong, and articulates with the corresponding facet on the surface of the calcaneus. The middle calcaneal articular surface (Figs. 4-222; 4-224) is small and oval, and articulates with the facet on the sustentaculum tali of the calcaneus.

FIG. 4-222. Left talus. Distal aspect.

The **medial surface** of the body is continuous superiorly with the trochlea and presents a pear-shaped articular facet for the medial malleolus (Figs. 4-221, 4-223). Below the articular surface is a rough depression for the attachment of the deep portion of the deltoid ligament of the ankle joint.

The **lateral surface** of the body, which also is continuous with the trochlea, carries a large triangular facet for articulation with the lateral malleolus (Figs. 4-221; 4-224). Anteriorly, there is a rough depression for the attachment of the anterior talofibular ligament. Between the posterior half of the lateral border of the trochlea and the posterior part of the base of the fibular articular surface is a triangular facet, which comes into contact with the transverse inferior tibiofibular ligament during flexion of the ankle joint. Below the base of this facet is a groove that affords attachment to the posterior talofibular ligament.

Posteriorly, the surface of the body of the talus is narrow and is traversed by a groove for the tendon of the flexor hallucis longus, which lies between two tubercles (Fig. 4-223). Lateral to the groove is a prominent tubercle, the **posterior process**, to which the posterior talofibular ligament is attached. This process is sometimes separated from the rest of the talus, and is then known as the **os trigonum**. Medial to the groove is a second less prominent tubercle to which attaches the medial talocalcaneal ligament.

The **neck of the talus** is directed forward and medially and is the constricted portion of the bone between the body and the head (Figs. 4-223; 4-224). Its superior and medial surfaces are rough for the attachment of ligaments. Its lateral surface is concave and is continuous below with a deep groove, the sulcus tali. Together with the calcaneus this groove forms the tarsal sinus for the interosseous talocalcaneal ligament.

The **head of the talus** is the rounded anterior end of the bone (Figs. 4-223; 4-224). It is directed distally and oriented slightly downward and medially. The **anterior** or **distal surface** of the head is covered by a large, oval, convex facet for articulation with the navicular. Its **inferior surface** (Fig. 4-222) has two facets, which are best seen in the fresh condition. Medially and anterior to the middle calcaneal facet is a semi-oval surface that rests on the plantar calcaneonavicular ligament. Laterally is located the flattened

FIG. 4-223. Left talus. Medial surface.

**anterior calcaneal articular surface**, which articulates with the facet on the superior surface of the anteromedial part of the calcaneus.

**Articulations.** The talus articulates with four bones: tibia, fibula, calcaneus, and navicular.

**THE CALCANEUS.** The calcaneus (Figs. 4-225 to 4-228) is the largest and strongest bone in the foot. It is situated in the posterior part of the foot and extends backward beyond the tibia and fibula to form the heel. The calcaneus serves to transmit the weight of the body to the ground and provides a strong lever for the muscles of the calf. It is somewhat cuboidal, with its long axis directed forward and laterally, and presents six surfaces for examination. These are the **superior, distal, lateral, medial, anterior, and posterior surfaces**.

The **superior or proximal surface** (Fig. 4-225) extends behind onto the portion of the calcaneus that forms the heel. It varies in

length in different individuals and is concave from front to back and convex from side to side. It is divisible into two parts, anterior and posterior. The **anterior part** contains three facets which are oriented proximally for articulation with the talus. The **posterior articular surface** is the largest of the three and is oval in shape and faces somewhat anteriorly. Medial to this facet is the **middle articular surface**, which is supported by the sustentaculum tali. The **anterior articular facet** is anterior and lateral to the middle facet and is in close proximity or joined with it. All three facets articulate with those of similar name on the distal surface of the talus. The **calcaneal sulcus** is a deep depression between the posterior and middle articular facets. In the intact foot it combines with a similar groove on the talus, called the **sulcus tali**, to form the **tarsal sinus** which contains the interosseous talocalcaneal ligament. Anterior and lateral to the calcaneal sulcus and the three articular facets, the rough surface provides attachment

FIG. 4-224. Left talus. Lateral surface.

FIG. 4-225. Left calcaneus. Superior or proximal surface.

FIG. 4-226. Left calcaneus. Distal or plantar surface.

for ligaments and for the origin of the extensor digitorum brevis. The posterior part of the superior surface is a rather smooth convex area extending from the articular facets to the calcaneal tuberosity.

The **distal** or **plantar surface** (Fig. 4-226) is wider behind than in front and convex from side to side. It is bounded posteriorly by a transverse elevation, the **calcaneal tuberosity**, which is depressed in the middle and prolonged on each side into a process. The **lateral process**—small, prominent, and rounded—gives origin to part of the abductor digiti minimi. The **medial process** is broader and larger, and gives attachment by its prominent medial margin to the abductor hallucis, the flexor digitorum brevis, and the plantar aponeurosis. The depression between the processes gives origin to the remainder of the abductor digiti minimi. The rough surface anterior to the processes gives attachment to the long plantar ligament, and to the lateral head of the quadratus plantae muscle. The plantar calcaneocuboid ligament is attached to a prominent tubercle nearer the anterior part of this surface, as well as to a transverse groove anterior to the tubercle.

The **lateral surface** (Fig. 4-227) is broad behind and narrow in front, flat, and almost subcutaneous. At its upper and anterior part, the lateral surface gives attachment to the lateral talocalcaneal ligament. Near its center is a tubercle for the attachment of the calcaneofibular ligament. Anterior to the tubercle is a narrow surface marked by two oblique grooves and separated by an elevated ridge, the **peroneal trochlea**, which varies much in size in different bones. The superior groove transmits the tendon of the peroneus brevis, while the inferior groove transmits that of the peroneus longus.

The **medial surface** is deeply concave, and the concavity is made more apparent by the prominent medial process of the calcaneal tuberosity posteriorly and the overhanging horizontal eminence, the **sustentaculum tali**, anterosuperiorly (Fig. 4-228). Within this hollow course the plantar vessels and nerves into the sole of the foot. The medial surface affords origin to the medial head of the quadratus plantae muscle, while the sustentaculum tali gives attachment to a slip of the tendon of the tibialis posterior. The superior surface of the sustentaculum tali contains the facet for articulation with the middle

FIG. 4-227. Left calcaneus. Lateral surface.

calcaneal articular surface of the talus. The *inferior surface* is grooved for the tendon of the flexor hallucis longus; its *anterior margin* gives attachment to the plantar calcaneonavicular ligament, and its *medial margin* to a part of the deltoid ligament of the ankle joint.

The **anterior surface** of the calcaneus (Fig. 4-226) is small and somewhat triangular in shape. It consists almost entirely of a facet for articulation with the cuboid bone. The plantar calcaneonavicular ligament is attached to its medial border.

The **posterior surface** protrudes as the prominence of the heel (Figs. 4-226; 4-228). It is divisible into three areas. The *inferior area* is rough and covered by the fatty, fi-

brous tissue of the heel. The *middle area* also is rough and forms the calcaneal tuberosity onto which inserts the tendo calcaneus and plantaris. The *superior portion* is smooth, and is covered by a bursa that intervenes between it and the tendo calcaneus.

**Articulations.** The calcaneus articulates with two bones: the talus and cuboid.

**CUBOID BONE.** The cuboid bone (Figs. 4-229; 4-230) is placed on the lateral aspect of the foot, distal to the calcaneus and proximal to the fourth and fifth metatarsal bones. The **dorsal surface** is directed laterally and is roughened for the attachment of ligaments. The **plantar surface** presents a deep

FIG. 4-228. Left calcaneus. Medial surface.

FIG. 4-229. The left cuboid. Anteromedial view.

FIG. 4-230. The left cuboid. Posterolateral view.

oblique groove, the **sulcus for the peroneus longus tendon**. This groove is bounded posteriorly by a prominent ridge, to which the long plantar ligament is attached. This ridge ends laterally in the **tuberosity of the cuboid bone**, the surface of which presents an oval facet over which a sesamoid bone or a cartilage in the tendon of the peroneus longus glides. The surface of bone posterior to the groove is rough, for the attachment of the plantar calcaneocuboid ligament, a few fibers of the flexor hallucis brevis, and a fasciculus from the tendon of the tibialis posterior. The **lateral surface** presents a deep notch formed by the commencement of the peroneal sulcus. The **posterior or proximal surface** is smooth and triangular in shape for articulation with the anterior surface of the calcaneus (Fig. 4-230). Its medial plantar angle projects posteriorly as a process that underlies and supports the anterior end of the calcaneus. The **anterior or distal surface** (Fig. 4-229) is divided by a vertical ridge into two facets: the medial facet is quadrilateral in shape and articulates with the fourth metatarsal; the lateral is triangular in shape and articulates with the fifth. The **medial surface** is broad and irregularly quadrilateral in shape. It presents at its middle and superior

part a smooth oval facet for articulation with the lateral cuneiform. Posterior to this is occasionally seen a smaller facet for articulation with the navicular. The remainder of this surface is nonarticular, but it is roughened for the attachment of strong interosseous ligaments.

**Articulations.** The cuboid articulates with four bones: the calcaneus, lateral cuneiform, and fourth and fifth metatarsals. Occasionally it articulates with a fifth bone, the navicular.

**NAVICULAR BONE.** The navicular bone (Figs. 4-231; 4-232) is situated at the medial side of the tarsus, between the talus proximally and the cuneiform bones distally. The **anterior or distal surface** is convex from side to side and subdivided by two ridges into three facets, for articulation with the three cuneiform bones (Fig. 4-231). The **posterior or proximal surface** is oval and concave and articulates with the rounded head of the talus. The **dorsal surface** is convex and rough for the attachment of ligaments. The **plantar surface** is irregular, and also rough for the attachment of ligaments. The **medial surface** presents the rounded **navicular tuberosity**, the lower part of which affords the

FIG. 4-231. The left navicular. Anterior or distal view.

FIG. 4-232. The left navicular. Posterior or proximal view.

principal attachment to the tendon of the tibialis posterior. The **lateral surface** is rough and irregular for the attachment of ligaments, and occasionally presents a small facet for articulation with the cuboid bone.

**Articulations.** The navicular articulates with four bones: the talus and the three cuneiforms. Occasionally it articulates with a fifth bone, the cuboid.

**MEDIAL CUNEIFORM BONE.** The medial cuneiform (wedge-shaped) bone is the largest of the three cuneiforms (Figs. 4-233; 4-234). It is situated on the medial side of the foot, between the navicular proximally, and the base of the first metatarsal distally. The **medial surface** is subcutaneous, broad, and quadrilateral, and at its anterior plantar angle is a smooth oval impression, into which part of the tendon of the tibialis anterior is inserted (Fig. 4-233). The rest of its extent is rough for the attachment of ligaments. The **lateral surface** is concave, presenting along its superior and posterior borders a narrow L-shaped surface which articulates with the intermediate cuneiform. The dorsal and distal part of the lateral surface presents a small facet which articulates with the medial surface of the base of the second metatarsal bone (Fig. 4-234). The rest of this surface is rough for the attachment of ligaments and part of the tendon of the peroneus longus. The **anterior or distal surface** is kidney-shaped and articulates with the first metatarsal bone. The **posterior or proximal surface** is triangular and concave and articulates with the most medial and largest of the three facets on the anterior surface of the navicular. The **plantar surface** is rough and

FIG. 4-233. The left medial cuneiform. Medial aspect.

FIG. 4-234. The left medial cuneiform. Lateral aspect.

forms the base of the wedge. At its posterior part is a tuberosity for the insertion of part of the tendon of the tibialis posterior. More anteriorly and laterally a slip from the tendon of the tibialis anterior also inserts on this surface. The **dorsal surface** is the narrow end of the wedge and is rough for the attachment of ligaments.

**Articulations.** The first cuneiform articulates with four bones: the navicular, intermediate cuneiform, and first and second metatarsals.

**INTERMEDIATE CUNEIFORM BONE.** The intermediate cuneiform bone (Figs. 4-235; 4-236) is the smallest of the three cuneiforms and presents a regular wedge shape, the thin end being the plantar. It is situated between the other two cuneiform bones and articulates with the navicular proximally and the second metatarsal distally. Thus, the **anterior or distal surface**, triangular in form, articulates with the base of the second metatarsal bone. The **posterior or proximal surface**, also triangular in shape, articulates with the intermediate facet on the anterior surface of the navicular. The **medial surface**

FIG. 4-235. The left intermediate cuneiform. Medial and distal view.

**FIG. 4-236.** The left intermediate cuneiform. Lateral and proximal view.

carries an L-shaped articular facet, running along the superior and posterior borders, for articulation with the medial cuneiform (Fig. 4-235); it is rough in the rest of its extent for the attachment of ligaments. The **lateral surface** presents posteriorly a smooth facet for articulation with the lateral cuneiform bone (Fig. 4-236). The **dorsal surface** forms the base of the wedge; it is quadrilateral and rough for the attachment of ligaments. The **plantar surface**, sharp and tuberculated, is also rough for the attachment of ligaments, and for the insertion of a slip from the tendon of the tibialis posterior.

**Articulations.** The intermediate cuneiform articulates with four bones: the navicular, medial and lateral cuneiforms, and second metatarsal.

**LATERAL CUNEIFORM BONE.** The lateral cuneiform bone (Figs. 4-237; 4-238) is also wedge-shaped and interposed between the cuboid and the intermediate cuneiform in the distal row of tarsal bones. The **distal or anterior surface** of the lateral cuneiform bone articulates with the base of the third metatarsal. Its **proximal or posterior surface** articulates with the lateral facet on the anterior surface of the navicular, and is rough inferiorly for the attachment of ligamentous fibers. The **medial surface** (Fig. 4-237) pre-

**FIG. 4-237.** The left lateral cuneiform. Medial and proximal aspect.

sents a distal and a proximal articular facet, separated by a rough depression. The distal facet, sometimes divided, articulates with the lateral aspect of the base of the second metatarsal bone. The proximal facet skirts the proximal margin and articulates with the intermediate cuneiform. The rough depression separating the articular facets gives attachment to an interosseous ligament. The **lateral surface** (Fig. 4-238) also presents two articular facets, separated by a rough nonarticular area. The distal facet, situated at the superior angle of the bone, is small and semi-oval, and articulates with the medial side of the base of the fourth metatarsal bone. The proximal and larger facet is triangular or oval, and articulates with the cuboid. The rough, nonarticular area between these serves for the attachment of an interosseous ligament. The three facets for articulation with the three metatarsal bones are continuous with one another; those for articulation with the intermediate cuneiform and navicular are also continuous, but that for articulation with the cuboid is usually separate. The **dorsal surface** is rectangular in shape and prolonged proximally, forming the base of the wedge. The **plantar surface** is the narrow, rounded margin of the wedge, and serves for the attachment of part of the tendon of the tibialis posterior, part of the flexor hallucis brevis, and for ligaments.

**Articulations.** The lateral cuneiform articulates with six bones: the navicular, intermediate cuneiform, cuboid, and second, third, and fourth metatarsals.

## THE METATARSUS

The **metatarsus** consists of five bones situated between the tarsal bones and the phalanges (Figs. 4-219; 4-220; 4-245; 4-246). They

**FIG. 4-238.** The left lateral cuneiform. Lateral and distal aspect.

are numbered from one to five from the medial side. Thus, the first metatarsal is that which articulates with the phalanges of the large toe, while the fifth metatarsal joins the phalanges of the small toe. Similar to the metacarpals, each metatarsal is a long bone in miniature and presents for examination a base, body, and head.

**COMMON CHARACTERISTICS OF THE METATARSAL BONES.** The **body** is long and slender, tapers gradually from the tarsal to the phalangeal extremity, and is curved longitudinally, so as to be convex dorsally and concave on the plantar aspect. The **base** or **proximal extremity** is wedge-shaped, articulating with the tarsal bones and, by its sides, with the contiguous metatarsal bones. The **dorsal** and **plantar surfaces** of the metatarsals are rough for the attachment of ligaments. The **head** or **distal extremity** articulates with the proximal phalanx of each toe and presents a convex articular surface, the plantar portion of which extends farther proximally than the dorsal. The sides of the heads are flattened, and on each is a depression, surmounted by a tubercle, for ligamentous attachment. The plantar surface of the heads is grooved anteroposteriorly for the passage of the flexor tendons, and marked on either side by an articular eminence continuous with the distal articular surface.

**CHARACTERISTICS OF THE INDIVIDUAL METATARSAL BONES.** The individual metatarsal bones possess distinctive anatomical features which allow them to be readily identified.

**First Metatarsal Bone.** The first metatarsal bone (Fig. 4-239) is remarkable for its great thickness and is the shortest of the metatarsal bones. The **body** or **shaft** is strong, and is markedly prismatic in form. Its lateral surface is triangular and flat and gives origin to the medial head of the first dorsal interosseous muscle. The **base** presents, as a rule, no articular facets on its sides, but occasionally on the lateral aspect there is an oval facet that articulates with the second metatarsal. Its proximal articular surface is large and kidney-shaped for articulation with the medial cuneiform bone. The circumference of this articular surface is grooved, for the tarsometatarsal ligaments. Medially it receives the insertion of part of the tendon of the tibialis anterior, and laterally it presents a rough oval prominence for the insertion of the tendon of the peroneus longus. The **head**

FIG. 4-239. The left first metatarsal bone. A, Medial aspect. B, Lateral aspect.

is large and on its plantar surface are two grooved facets, on which glide sesamoid bones. The facets are separated by a smooth central elevation.

**Second Metatarsal Bone.** The second metatarsal bone (Fig. 4-240) is the longest of the metatarsal bones, being prolonged proximally to fit into the recess formed by the three cuneiform bones. Its **base** is broad dorsally, narrow and rough below. It presents four articular surfaces: a posterior triangular facet for articulation with the intermediate cuneiform; one at its medial surface for articulation with the medial cuneiform; and two on its lateral surface separated by a rough nonarticular interval. Each of these lateral articular surfaces is divided into two facets by a vertical ridge. The two anterior facets articulate with the third metatarsal, while the two posterior (sometimes continuous) articulate with the lateral cuneiform. A fifth facet is occasionally present for articulation with the first metatarsal. It is oval in shape, and is situated on the medial side of the body, just distal to the base. The plantar surface of the base of the second metatarsal affords insertion to a slip of the tibialis posterior tendon. From the medial surface of the shaft arises the lateral head of the first dorsal

**FIG. 4-240.** The left second metatarsal bone. A, Medial aspect. B, Lateral aspect.

interosseous muscle, while the lateral surface gives origin to the medial head of the second dorsal interosseous.

**Third Metatarsal Bone.** The third metatarsal bone (Fig. 4-241) is shorter than the second, and its **base** articulates proximally with the lateral cuneiform by means of a triangular smooth surface. Medially the base articulates, by two facets, with the second metatarsal, and laterally, by a single facet, with the fourth metatarsal. This last facet is situated at the dorsal angle of the base. The base allows insertion of a small slip from the tibialis posterior. From the shaft arise the lateral head of the second dorsal interosseous muscle and the medial head of the third dorsal interosseous muscle, and from the plantar surface arises the first plantar interosseous muscle.

**Fourth Metatarsal Bone.** The fourth metatarsal bone (Fig. 4-242) is smaller in size than the preceding. Its **base** presents an oblique quadrilateral surface for articulation with the cuboid. A smooth facet on the medial side is divided by a ridge into an anterior portion for articulation with the third

**FIG. 4-241.** The left third metatarsal bone. A, Medial aspect. B, Lateral aspect.

**FIG. 4-242.** The left fourth metatarsal bone. A, Medial aspect. B, Lateral aspect.

metatarsal, and a posterior portion for articulation with the lateral cuneiform. On the lateral side a single facet is for articulation with the fifth metatarsal. The shaft of the fourth metatarsal gives origin on its medial aspect to the lateral head of the third dorsal interosseous muscle and on its lateral aspect to the medial head of the fourth dorsal interosseous muscle. Additionally, on its plantar surface arises the second plantar interosseous muscle.

**Fifth Metatarsal Bone.** The fifth metatarsal bone (Fig. 4-243) is recognized by a rough eminence, the **tuberosity**, on the lateral aspect of its base. The base articulates posteriorly with the cuboid and medially with the fourth metatarsal. On the medial part of its dorsal surface is inserted the tendon of the peroneus tertius and on the dorsal surface of the tuberosity that of the peroneus brevis. A strong band of the plantar aponeurosis connects the projecting part of the tuberosity with the lateral process of the tuberosity of the calcaneus. The plantar surface of the base is grooved for the tendon of the abductor digiti minimi, and gives origin to the flexor digiti minimi brevis. On the medial aspect of the shaft arises the lateral head of the fourth dorsal interosseous muscle, while from its plantar aspect arises the third plantar interosseous muscle.

FIG. 4-243. The left fifth metatarsal bone. A, Medial aspect. B, Lateral aspect.

**ARTICULATIONS.** The base of each metatarsal bone articulates with one or more of the tarsal bones, and the head of each metatarsal articulates with the first phalanx of the corresponding toe. The first metatarsal articulates with the medial cuneiform, the second with all three cuneiforms, the third with the lateral cuneiform, the fourth with the lateral cuneiform and the cuboid, and the fifth with the cuboid. In addition the bases of the metatarsals articulate with those of adjacent metatarsals.

#### PHALANGES OF THE FOOT

The **phalanges** of the foot (Figs. 4-219; 4-220; 4-245; 4-246) correspond in number and general arrangement to those of the hand. There are two in the great toe and three in each of the other toes. They differ from the phalanges of the hand because of their smaller size. The shafts are much reduced in length and they are laterally compressed, especially the phalanges of the proximal row.

**PROXIMAL ROW** (first row). The phalanges of the proximal row are compressed in the middle and expanded at each extremity. The **shafts** are convex dorsally and concave on their plantar surface. The **base** is concave, articulating with the head of the corresponding metatarsal bone. The **head** presents a trochlear surface for articulation with the middle phalanx.

**MIDDLE ROW** (second row). The phalanges of the second row are remarkably small and short, but somewhat broader than those of the proximal row.

**DISTAL ROW.** The **ungual phalanges** resemble those of the fingers, but are smaller and more flattened. Each presents a broad base for articulation with the corresponding bone of the middle row, and an expanded distal extremity, called the **ungual tuberosity**, for the support of the toenail dorsally and the pulp of the tip of the toe distally.

**ARTICULATIONS.** In the second, third, fourth, and fifth toes, the phalanges of the proximal row articulate with the metatarsal bones proximally and the middle phalanges distally. The middle phalanges articulate with the proximal and distal phalanges, while the ungual phalanges articulate with the middle. The first toe has but two phalanges, the proximal articulates with the first metatarsal bone and with the distal phalanx. The distal phalanx articulates only with the proximal phalanx.

**OSSIFICATION OF THE BONES OF THE FOOT** (Fig. 4-244). The **tarsal bones** are each ossified from a

FIG. 4-244. Plan of ossification of the foot.

single center, except the calcaneus, which has an epiphysis for its posterior extremity. The centers make their appearance in the following order: *calcaneus*, between the fourth and seventh month of fetal life; *talus*, about the sixth month or earlier; *cuboid*, at the ninth month; *lateral cuneiform*, during the first year; *medial cuneiform*, in the second year; *intermediate cuneiform* and *navicular*, in the third year. The epiphysis for the posterior extremity of the calcaneus appears at the eighth year and unites with the rest of the bone soon after puberty. The posterior process of the talus is sometimes ossified from a separate center and may remain distinct from the main mass of the bone. When this occurs, it is named the *os trigonum*.

The **metatarsal bones** corresponding to the second, third, fourth, and fifth toes are each ossified from two centers, one for the body or shaft, and one for the head. The first metatarsal ossifies from centers for its shaft and base. Ossification commences in the centers of the shafts during the ninth or tenth week and extends toward either extremity. The ossification center of the epiphysis at the base of the first

metatarsal appears about the third year, while the centers for the heads of the other bones appear between the fifth and eighth years. The epiphyses unite with the shafts between the eighteenth and twentieth years.

The **phalanges** are each ossified from two centers, a primary center for the body or shaft and an epiphysal center for the base. The primary ossification centers for the shafts of the proximal and distal phalanges appear between the eighth and twelfth fetal week, while those for the shafts of the middle phalanges appear at about the sixteenth intrauterine week. Epiphysal centers in the bases of the phalanges appear between the second and tenth years. The epiphyses join the shafts at about the eighteenth year.

### SESAMOID BONES

**Sesamoid bones** are rounded formations of bone embedded in certain tendons where the latter are subjected to com-

pression as well as to their usual tensile stresses. Generally they measure only a few millimeters in diameter; however, the patella is an example of a large sesamoid bone which is consistently observed in the tendon of the quadriceps femoris muscle. The sesamoid bones are genuine parts of the skeleton and are found in the fetus as well as in phylogenetically distantly related animal forms, often in greater abundance than in the adult human body. The precise function of sesamoid bones is uncertain, and indeed may vary at different sites. Their association with the physical stresses, tensions, and friction produced by tendons is generally acknowledged.

In the *upper limb*, the sesamoid bones occur normally only in relation to the joints of the palmar surface of the hand. The two most constant are in the tendons of the two heads of the flexor pollicis brevis at the metacarpophalangeal joint, the medial or deep head having the larger bone. A corresponding one in the flexor digiti minimi brevis is frequently present at the metacarpophalangeal joint and one (or two) at the same joint of the index finger. Additionally, a sesamoid bone is often found in the insertion tendon of the adductor pollicis muscle. Sesamoids are also found occasionally at the metacarpophalangeal joint of the middle and ring fingers, at the interphalangeal joint of the thumb, and at the distal interphalangeal joint of the index finger. Sesamoid bones apart from joints are seldom found in the tendons of the upper limb, although one is seen at times in the tendon of the biceps brachii opposite the radial tuberosity.

In the *lower limb*, the largest sesamoid bone is the patella, in the tendon of the quadriceps femoris at the knee. Two constant sesamoids occur in the tendons of the flexor hallucis brevis at the metatarsophalangeal joint, the medial being the larger. One is occasionally found at the same joint of the second and fifth toes, or even of the third and fourth toes, and one at the interphalangeal joint of the great toe. Sesamoid bones in the lower extremity are seen in several tendons at sites other than at joints. One is in the tendon of the peroneus longus, where it glides on the cuboid. Another, appearing late in life, is found in the tendon of the tibialis anterior, opposite the smooth facet of the medial cuneiform bone. Other sesamoid bones are found in the tendon of

the tibialis posterior, opposite the medial side of the head of the talus; in the lateral head of the gastrocnemius, behind the lateral condyle of the femur; and in the tendon of the psoas major, where it glides over the pubis. Occasionally, sesamoid bones are also found in the tendons that wind around the medial and lateral malleoli, and in the tendon of the gluteus maximus, as it passes over the greater trochanter.

#### COMPARISON OF THE BONES OF THE HAND AND FOOT

The hand and foot are constructed on somewhat similar principles, each consisting of a proximal part, the carpus or the tarsus, an intermediate portion, the metacarpus or the metatarsus, and a distal portion, the phalanges. The *proximal part* consists of a series of more or less cubical bones which allow a slight amount of gliding on one another and are chiefly concerned in distributing forces transmitted to or from the bones of the arm or leg. The *intermediate part* is made up of slightly movable long bones which assist the carpus or tarsus in distributing forces and also give greater breadth for the reception of such forces. The separation of the individual bones from one another allows the attachments of the interosseous muscles and protects the dorsal-to-palmar and dorsal-to-plantar vascular anastomoses. The *distal portion* is the most movable, and its separate elements enjoy a varied range of movements, the most common of which are flexion and extension.

Although comparable in structure, the hand and foot show modifications in their detailed anatomy which meet the requirements of their very different functions. In essence, the hand serves as the appendage of the upper extremity and is controlled in its function as a grasping, holding, and presenting organ. In contrast, the foot forms a firm basis of support for the body in the erect posture, and is therefore more solid. Its component parts are less movable than are those of the hand.

In the case of the phalanges the differences are readily noticeable. Those of the foot are smaller and their movements are more limited than those of the hand. Very much more marked is the difference between the metacarpal bone of the thumb and

the metatarsal bone of the great toe. The *metacarpal bone of the thumb* is constructed to permit great mobility, is directed at an acute angle from that of the index finger, and is capable of a considerable range of movement at its articulation with the carpus. The thumb is rotated, thereby allowing for its ability to oppose each of the other fingers. The *metatarsal bone of the great toe* assists in supporting the weight of the body, is constructed with great solidity, lies parallel with and in the same plane as the other metatarsals, and has a very limited degree of mobility.

The carpus is small in proportion to the size of the rest of the hand. The carpal bones are placed in line with the forearm, and form a transverse arch, the concavity of which constitutes a bed for the flexor tendons entering the hand from the forearm and for the palmar vessels and nerves. In contrast, the tarsus is large and forms a considerable part of the foot. It is placed at right angles to the leg, a position that is almost peculiar to man and facilitates his erect posture. In order to allow the support of the body and to distribute its weight properly, the tarsus, metatarsus, and phalanges of the foot are constructed as a series of both **longitudinal** and **transverse arches**, the nature of which will be considered after the articulations of the foot have been described (Chapter 5).

## Histologic Structure of Connective Tissues

The connective tissues are a broadly distributed group of body elements of many varieties derived from embryonic mesoderm. Widely ranging structures, such as fascia, fat, ligaments, and tendons are formed of connective tissue, as are the more specialized tissues of bone, cartilage, and blood. Connective tissue always contains in various proportions three principal components: **cells**, **extracellular fibers**, and **interstitial ground substance**. The extracellular fibers and ground substance form an intercellular matrix which may vary in consistency. It may be liquid, as in tissue fluid, or gelatinous, or it may be solid as in bone and cartilage. The cellular components of connective tissue are surrounded by the intercellular matrix. There are a variety of

connective tissue cell types, both fixed and wandering, but all are derived from mesodermal elements.

**CONNECTIVE TISSUE CELLS.** The most numerous fixed cells in connective tissue and those principally responsible for the formation of extracellular fibers and ground substance are the **fibroblasts** (Fig. 4-245). Some authors, when discussing the mature body, refer to these same cells as **fibrocytes**; however, due to the dynamic, ever-changing conditions within the tissues of the adult as well as the fetus, it is customary, regardless of age, to call them **fibroblasts**. Fibroblasts appear frequently along strands of collagen. They are polymorphic, but frequently appear as long, slender cells with several cytoplasmic processes, which give them a spindle-like appearance. Their nuclei are relatively large, oval-shaped, and basophilic, and their cytoplasm contains the usual organelles such as mitochondria. Although they have little or no visible specializations when found in fibrous connective tissue, they may receive specific names such as **osteoblasts** and **osteocytes**, or **chondroblasts** and **chondrocytes** in bone and cartilage.

Many other types of cells are found in the connective tissues. One of the more common is the ubiquitous **histiocyte** or **fixed macrophage** (Fig. 4-246). This cell type possesses a remarkable ability to ingest foreign particulate matter and, because of this property, is similar to other phagocytic cells occurring in several organs. The many phagocytic cell types throughout the body comprise the

**Fig. 4-245.** Fibroblasts along strands of collagen in the loose connective tissue of the prepubertal female breast. Hematoxylin and eosin stain, 600  $\times$ .

**FIG. 4-246.** Two macrophages or histiocytes among other elements in this subcutaneous connective tissue spread from a rat. The animal had been injected with trypan blue intraperitoneally in order to demonstrate the phagocytic property of these cells. Note the ingested dye within the cytoplasm. Resorcin-fuchsin and axocarmine. 1000  $\times$ .

great phagocytic system called the **reticulo-endothelial system**. Another cell type found in connective tissue is the **mast cell** (Fig. 4-247). These are widely distributed throughout the body and are abundantly found along the course of small blood vessels. The

**FIG. 4-247.** Two mast cells from a subcutaneous connective tissue spread stained with neutral red. Note that the cytoplasm is filled with granules. 1800  $\times$ .

cytoplasm of mast cells is filled with granules believed to contain at least three important substances: **heparin**, which acts as an anticoagulant; **histamine**, which is a vasodilator and increases capillary permeability; and **serotonin**, which acts as a vasoconstrictor. Mast cells react to tissue injury by the release of their granules into the surrounding tissue. **Plasma cells**, which are known to contribute to the formation of antibodies, are at times seen in connective tissue, but can more readily be found in lymphatic organs and in subepithelial lymphatic tissue of digestive and respiratory organs. Other cells, such as the **polymorphonuclear leukocytes**, accumulate in an area where there is acute inflammation, and **lymphocytes** where the disease is more chronic. Occasionally, the other types of white blood cells—**monocytes**, **eosinophils**, and **basophils**—are seen in connective tissue, but red blood corpuscles are usually not found in the connective tissue unless there has been an injury to the blood vessels.

**CONNECTIVE TISSUE FIBERS.** Three types of fibers are found in adult connective tissue—collagenous, reticular, and elastic. Of these, the **collagenous fibers** (Fig. 4-248) are the most abundant. Fibroblasts produce molecules of tropocollagen which then assemble to form fine fibrils of collagen. The nature and arrangement of collagen lend both great strength and flexibility to the formation of fibrous connective tissue. Collagenous fibers are white and form the bulk of tendons, ligaments, and fascia, where they are pliable

**FIG. 4-248.** Collagen fibers stained in a teased spread of loose connective tissue. Hematoxylin and eosin. 250  $\times$ .

and enduring, but they resist stretching and are practically not extensible. **Reticular fibers** (Fig. 4-249) are found forming the networks around fat cells and beneath the endothelium of capillaries, as well as forming the fibrous supporting structure of lymphoid and blood-forming organs. They are argyrophilic and are composed of fibrils similar to collagenous fibers, but of a smaller diameter. The fibers appear coated with polysaccharides, which probably give them the property of reacting with silver salts. **Elastic fibers** (Fig. 4-250) contain protein and differ in color from collagen, appearing yellow in the fresh state. Elastic fibers are thin and wavy, branch repeatedly, and in connective tissue form a network among the collagenous fibers and cells. They vary in thickness and chemically consist of elastin. They stretch easily but allow the tissue to reassume its original form following stretching. Generally less numerous than collagen in connective tissue, elastic fibers are plentiful in the walls of arteries.

**GROUND SUBSTANCE.** The **ground substance** or **matrix** surrounding both cells and fibers may be fluid, semifluid, or solid, and although not composed of living material such as protoplasm, it is not inert. In ordinary fibrous connective tissue, the ground substance is a viscous solution. It contains

**FIG. 4-249.** Reticular fibers impregnated with silver are seen forming a branching network within a lymph node. 900  $\times$ .

**FIG. 4-250.** Elastic fibers as observed in the wall of the human aorta. Stained with resorcin fuchsin. 144  $\times$ .

long chained carbohydrates called *acid mucopolysaccharides* (more accurately called *glycosaminoglycans*) of which *hyaluronic acid* and *chondroitin sulfuric acid* are the most common. Ground substance has a great capacity to bind and hold water. Through it substances are diffused between the capillaries and the cells of tissues and organs, making it a highly important metabolic interface in the body.

### CONNECTIVE TISSUE TYPES

The various types of so-called proper connective tissue are classified according to the nature of their cellular and intercellular components. When the proportion of fibers is highly predominant over the cellular and intercellular elements, the tissue is referred to as **dense fibrous connective tissue**. When the fibers are oriented in a parallel manner, the tissue is called **dense regular connective tissue**, in contrast to that containing randomly oriented fiber bundles, which is called **dense irregular connective tissue**. Differing from dense connective tissue, **loose fibrous connective tissue** is a fine network of loosely woven elements, in which the fibers are not densely packed. Also of importance are several other more special types of connective tissue—**reticular connective tissue**, **adipose tissue**, **mucous connective tissue**,

and elastic connective tissue. Cartilage and bone will be considered separately.

**DENSE FIBROUS CONNECTIVE TISSUE.** Dense regular connective tissue is the principal constituent forming the tendons, aponeuroses, and ligaments. The collagenous fibers are arranged in compact parallel bundles and impart a glistening white color that is characteristic of the tissue. Structures formed from dense regular connective tissue are pliable and inelastic, and withstand great tensional stress, particularly in one direction, but can endure little compressional stress. Dense irregular connective tissue has its collagenous fibers interwoven rather than arranged into parallel bundles. This tissue forms the fascial membranes, corium or dermis of the skin, periosteum, and capsules of organs. These structures are able to resist strong tensional stress in many directions and, in this respect, differ from the unidirectional resistance capacity of tendons and ligaments. As might be expected, the distinction between regular and irregular connective tissue is at times arbitrary. Some membranes have the collagenous bundles in layers rather than interwoven and thus may have a white, glistening appearance similar to that of aponeuroses, as for example in the dura mater and certain of the named fascias.

**Tendons** are white, glistening fibrous bands that attach muscles to bones. They vary in length and thickness, are sometimes round, sometimes flattened, of great tensile strength, flexible, and practically inelastic. They consist of collagenous bundles which

are firmly united together and whose fibrils have a parallel course (Fig. 4-251). The fibroblasts are arranged in linear fashion between the parallel collagenous bundles. Except where they are attached, the tendons have a sheath or delicate irregular fibrous and elastic connective tissue, and larger tendons have a stroma of thin internal septa as well. They are sparingly supplied with blood vessels, the smaller tendons presenting no trace of them in their interior. They are supplied with sensory nerves whose fibers have specialized terminations called the **neurotendinous endings of Golgi**, which mediate a special stereognostic sensibility.

**Aponeuroses** are fibrous membranes, of a pearly white color, iridescent, and glistening, and represent very much flattened tendons. They consist of closely packed, parallel, collagenous bundles, and by this characteristic may be differentiated from the fibrous membranes of fascia, which have their collagenous bundles more irregularly interwoven. An aponeurosis usually consists of several layers of collagenous bundles arranged in such a manner that the bundles of adjacent layers are oriented in different directions. Aponeuroses are only sparingly supplied with blood vessels.

**Ligaments** are structures that strengthen joints and tend to restrain abnormal movements. On the other hand, they are pliant and flexible so as to allow perfect freedom of movement of the joint in its normal directions. Ligaments resist tensions, and their collagenous bundles accordingly are

**Fig. 4-251.** Longitudinal section of a human tendon showing the parallel orientation of the collagenous bundles. Note also the linear orientation of the fibroblast nuclei. Hematoxylin and eosin. 170  $\times$ .

mainly parallel. They lack the glistening whiteness of tendons, however, because there is a greater admixture of elastic and fine collagenous fibers woven among the parallel bundles. Ligaments are as strong as tendons and have in addition a slight amount of elasticity. They are of different shapes and are formed as cords, bands, or sheets. Ligaments may be well-defined bands of fibers that appear as local thickenings in the capsule of a joint. In addition to capsular ligaments, others may be quite independent of the joint capsule. Their deep surface may form part of the synovial membrane of a joint, but their superficial surface is covered with a fibroelastic tissue that blends with the surrounding connective tissue. Certain ligaments are composed primarily of yellow elastic fibers. Examples are the *ligamenta flava*, which connect the laminae of adjacent vertebrae, and the *ligamentum nuchae* in the dorsal neck of grazing animals. In these cases the elasticity of the ligament is intended to act as a substitute for muscle power.

**Fascia** is the term used in gross anatomy for all dissectable fibrous connective tissue not specifically organized as tendons, aponeuroses, and ligaments. It varies in thickness and density according to functional demands, and is usually in the form of membranous sheets. In places where two fibrous sheets of fascia are easily separated, a loose areolar connective tissue intervenes. The site is frequently referred to as a fascial cleft. Often a fascial sheet may have a specific name; at other times it is referred to generally as *investing fascia*, *superficial fascia*, or *deep fascia*. Fascia separates muscles, invests blood vessels and nerves, forms a subcutaneous layer of tissue throughout the body, and contains between its fibers varying amounts of fat.

**LOOSE FIBROUS CONNECTIVE TISSUE.** Loose fibrous connective tissue is the most pervasive of all the connective tissues. It accompanies blood vessels and nerves throughout the body, extends into most organs, glands, and muscles, and is found beneath mucous and serous membranes (Fig. 4-252). It has a strong binding power, but is very pliable and somewhat stretchable. It contains elastic fibers among its collagenous bundles which are loosely interwoven and easily displaced, in contrast to the compact structure seen in dense connective tissue. Between the fibers

**FIG. 4-252.** Loose (areolar) connective tissue (stained blue) around blood vessels and between segments of the kidney. Note the extension of wisps of connective tissue between some of the tubules. Trichrome stain. 144  $\times$ .

there may be comparatively wide interstices or areolae which are sponge-like and filled with liquid ground substance or tissue fluid. When this tissue is more closely woven, as in the capsules of organs, it is called **fibroelastic tissue**. When it is loosely woven and weak, as in the fascial clefts, it is called **fibroareolar** or **areolar tissue**.

**RETICULAR CONNECTIVE TISSUE.** Reticular connective tissue is composed of delicate reticular fibrils woven into a loose meshwork which surrounds individual or small groups of cells not belonging to the connective tissue. Its most typical form is found in such organs as the spleen, liver, lymph nodes, and bone marrow, where the individual lymphocytes are retained in its meshes. The fibrils are difficult to see in the usually prepared histological slides stained with hematoxylin and eosin because they are masked by the cells. They can be made visible with silver impregnation, however, and in these preparations the delicate fibrils merge with the collagenous bundles of the capsule of the organ (Fig. 4-249). The same delicate meshwork of reticular fibrils surrounds individual muscle fibers, glandular acini, nerve fibers, and capillary blood ves-

sels in other parts of the body, but at these sites is usually given the specific name of reticular tissue. The cells of reticular connective tissue appear as primitive looking mesenchyme cells. Their processes course along the reticular fibers, and certain of these cells exhibit phagocytic properties.

**ADIPOSE TISSUE.** Adipose tissue is the name given to tissue in which there is an accumulation of connective tissue cells, each containing a large vesicle of fat (Fig. 4-253). In an obese individual these accumulations may occur wherever there is loose fibrous connective tissue. In all but emaciated individuals, however, they are found in certain areas where they act as packing or padding tissue. Examples of the latter are the orbit, perirenal fat pad, and various areas of the subcutaneous tissue. Adipose tissue is not inert and does not simply store fat over long periods of time. Fat cells show a considerable metabolic activity and there is a rapid and continuous turnover of lipid. They are able to synthesize triglycerides from free fatty acids and to store the lipid in the form of fat droplets which then are broken down again under the influence of

hormones. The storage and release of fat is importantly influenced by insulin and epinephrine.

### Cartilage

Cartilage is essentially a nonvascular tissue because it has no capillary network of its own, nor does it contain nerves. It is found in various parts of the body—in adult life chiefly in the joints, in the walls of the thorax, and in the walls of various tubular structures that must be kept permanently open, such as the larynx, trachea and bronchi, nose, and ears. In the fetus, at an early period, the greater part of the skeleton is cartilaginous. This temporary cartilage is eventually replaced by bone, in contradistinction to more permanent cartilage, which remains unossified during the whole of life.

Cartilage cells, called **chondrocytes**, are surrounded by a compact matrix. The nature of this matrix and the abundance and relative proportion of collagenous and elastic fibers it contains are used to distinguish three types of cartilage: **hyaline cartilage**, **yellow or elastic fibrocartilage**, and **white fibrocartilage**.

**HYALINE CARTILAGE.** Hyaline cartilage consists of a gristly mass with firm consistency, which is considerably elastic, translucent, and of a pearly blue color. Except where it coats the articular ends of bones, hyaline cartilage is covered externally by a fibrous membrane, the **perichondrium**, from the vessels of which it imbibes its nutritive substances. Histologically, hyaline cartilage is composed of cells of a rounded or bluntly angular form, lying in groups of two or more in a granular or almost homogeneous matrix (Fig. 4-254). These small clusters of chondrocytes are referred to as **isogenous groups**, because the several cells in each group are derived from a single chondrocyte. Chondrocytes in isogenous groups generally have straight outlines where they are in contact with each other, whereas the rest of their circumference is rounded. These cells contain a clear translucent cytoplasm in which is seen a well-developed endoplasmic reticulum. Their nuclei are rounded or ovoid, containing several nucleoli. The cavities in the matrix, which contain the chondrocytes, are called **cartilage lacunae**. The matrix around the lacunae containing the chondrocytes stains more basophilic because of its higher

**Fig. 4-253.** Ordinary fat cells showing the cytoplasmic rim which encloses large intracytoplasmic spaces that in life contained fat droplets. The fat has been extracted during tissue preparation. Hematoxylin and eosin. 900  $\times$ .

**FIG. 4-254.** Hyaline cartilage. Note the isogenous groups of chondrocytes separated by cartilage matrix. Photomicrograph taken of nasal alar cartilage. P, Perichondrium. (From Elias and Pauly, 1966.)

concentration of acid mucopolysaccharides. This more basophilic zone is termed the **territorial** or **capsular matrix**, while the remaining, less basophilic matrix is called the **interterritorial matrix**.

The matrix is translucent and appears grossly to be structureless or granular, resembling ground glass. However, ultrastructural and radioautographic studies have revealed that a significant part of the matrix of cartilage consists of fibrils, and these have the characteristics of collagen in articular cartilage. Further, it has been shown that chondrocytes form the precursors of the matrix. Belanger (1954) showed that radioactive sodium sulfate becomes incorporated first in chondrocytes and then in cartilage matrix. Studies by Revel and Hay (1963) have clinched this story. They showed the progressive incorporation of proline from

different cytoplasmic structures of chondrocytes into the territorial matrix adjacent to the lacunae. Eventually all the radioactive proline metabolized from the cells into the matrix.

Hyaline cartilage at the **articular surfaces** of bone shows no tendency to ossify. The matrix is finely granular and the cells are small and disposed parallel to the surface superficially, while more deeply and nearer the bone they are arranged in vertical rows. The free surface of articular cartilage, where it is exposed to friction, is not covered by perichondrium, although a layer of connective tissue continuous with the synovial membrane can be traced over a small part of its circumference. At this interface the cartilage cells are more or less branched and pass insensibly into the branched connective tissue elements of the synovial membrane. Articular cartilage forms a thin covering layer over the joint surfaces of the bones, and its elasticity enables it to break the force of concussions, while its smoothness affords ease and freedom of movement.

Cartilage at articular surfaces varies as much as 0.5 cm. or more, in thickness according to the shape of the bony surface on which it lies. When the bone is convex the cartilage is thickest at the center, the reverse being the case on concave articular surfaces. Cartilage appears to derive its nutriment partly from the vessels of the neighboring synovial membrane and partly from those of the bone upon which it is encapsulated. The vascularized tufts of osteogenic marrow in the cancellous bone dilate and form arches as they approach the cartilage layer, and then return into the substance of the bone.

The cells of the hyaline cartilage which compose the **cartilages of the ribs** are large, and the usually homogeneous matrix has a tendency to fibrous striation, especially in old age. In the thickest parts of the costal cartilages a few large vascular channels may be detected. At first sight this would appear to be an exception to the statement that cartilage is a nonvascular tissue, but this is not so because the vessels give no branches to the cartilage substance itself, and the channels rather should be looked on as involutions of the perichondrium. The xiphoid process and the cartilages of the nose, larynx, and trachea (except the epiglottis and corniculate cartilages of the larynx, which are composed of elastic fibrocartilage) resemble the costal

cartilages in their microscopic anatomy. The arytenoid cartilage of the larynx shows a transition from hyaline cartilage at its base to elastic cartilage at the apex.

Structures that are normally composed of hyaline cartilage are prone to calcify in old age. Their matrix becomes permeated by calcium salts without any appearance of true bone. This process often is manifested by the deposition of calcified crusts on the surfaces of the cartilage and occurs frequently in some cartilage such as that of the trachea and larynx and in the costal cartilages. At times it may, however, be succeeded by conversion into true bone.

**YELLOW OR ELASTIC FIBROCARILAGE.** Yellow or elastic fibrocartilage is more opaque than hyaline cartilage, and is more flexible and pliant. These characteristics are imparted by the elastic fibers embedded in the cartilage matrix (Fig. 4-255). The lacunae

containing the cartilage cells are rounded, similar to those of hyaline cartilage, and have a capsule of clear matrix. The cells are found singly or in isogenous groups. The elastic fibers may be sparsely scattered or densely arranged, and they course in all directions, interlacing into a network. The fibers at the periphery are continuous with the elastic fibers of the perichondrium. Elastic cartilage is found in the external ear, the cartilage of the auditory tube, the epiglottis, and the corniculate and cuneiform cartilages of the larynx.

**WHITE FIBROCARILAGE.** White fibrocartilage consists of a combination of dense collagenous fibers and cartilage cells in various proportions. To the former of these constituents it owes its flexibility and toughness, and to the latter its elasticity. The collagenous fibers are arranged in bundles, with cartilage cells between the bundles (Fig. 4-256). The

**FIG. 4-255.** Elastic cartilage of the epiglottis of a 13-year-old boy. Stained with elastin H, Delafield's hematoxylin and eosin. 435  $\times$ . (From Copenhagen, Bunge, and Bunge, 1971.)

**FIG. 4-256.** Fibrocartilage from human intervertebral disc. c.c., cartilage cell; c.f., collagenous fibrils embedded in cartilaginous matrix; c.l., cartilage lacuna. 1000  $\times$ . (Redrawn from Sobotta.)

cartilage cells are enclosed in capsules around which is a small concentrically striated area of hyaline matrix. To a certain extent the cells resemble those of tendons, but are distinguished from them by their surrounding matrix and by being less flattened. White fibrocartilage forms a number of structures which may be grouped as **interarticular**, **connecting**, **circumferential**, and **stratiform**.

The **interarticular fibrocartilages** (such as the menisci of the knee joint) are flattened fibrocartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints. They are free on both surfaces, usually thinner toward the center than at the circumference, and held in position by the attachment of their margins and extremities to the surrounding ligaments. The synovial surfaces of the joints are prolonged over them. They are found in the temporomandibular, sternoclavicular, acromioclavicular, wrist, and knee joints. Thus, they are found in those joints that are most exposed to violent concussion and subject to frequent movement. Their actual function is little

understood but it is conjectured that they (1) obliterate the intervals between opposed surfaces in their various motions; (2) increase the depths of the articular surfaces and give ease to the gliding movements; (3) moderate the effects of great pressure and deaden the intensity of the shocks to which the parts may be subjected; and (4) act to spread synovial fluid. The presence of interarticular fibrocartilages also serve to increase the variety of movement in a joint. Thus, in the knee joint, although it is a hinge joint in which, as a rule, only one variety of motion is permitted, there are two kinds of motion—angular movement and rotation. Angular movement takes place between the condyles of the femur and the interarticular cartilages, while rotation occurs between the cartilages and the head of the tibia.

The **connecting fibrocartilages** are interposed between the bony surfaces of those joints that have only slight mobility, as between the bodies of the vertebrae. At these sites the fibrocartilages form discs, which are closely adherent to the opposed surfaces. Each *intervertebral disc* is composed of concentric rings of fibrous tissue, with cartilaginous laminae interposed. The fibrous tissue predominates toward the disc circumference, while the cartilaginous material is more evident toward the center.

The **circumferential fibrocartilages** consist of rims of fibrocartilage, which surround the margins of some of the articular cavities, such as the *glenoidal labrum* of the hip, and of the shoulder. The annular lips serve to increase the articular surface of contact between the bones by deepening the articular cavities. They also protect the bony edge of the socket.

The **stratiform fibrocartilages** are those that form a thin coating to osseous grooves through which the tendons of certain muscles glide. Small masses of fibrocartilage are also developed in the tendons of some muscles, where they glide over bones, as in the tendons of the peroneus longus and tibialis posterior muscles.

### Bone

Like other connective tissues, bone consists of cells that are surrounded by fibers and ground substance. The calcification of its matrix into a hard and rigid substance that serves to support and protect the softer

body structures distinguishes it from other connective tissues. Additionally, the skeleton provides sites of attachment for the muscles that allow the organism motor expression, such as locomotion, as well as other bodily movements. Although bone may appear at first glance to be an inert tissue, it is, in fact, metabolically active and dynamic. Bone is a highly vascularized tissue and has an excellent capacity for self-repair.

### MACROSCOPIC STRUCTURE OF BONE

If a bone from an adult limb is sectioned longitudinally and examined grossly, it is found to be a tubular structure, the walls of which are formed of osseous material and the central cavity of which contains yellow or red **bone marrow**. The general contours of the bone resemble the enlarged fully grown model of its miniature prenatal form. Its surface, excepting the cartilage-covered articular ends, is closely invested by a fibrous, tough **periosteum**, which is highly vascularized and freely innervated. Other macroscopic features reveal that the shaft, or **diaphysis**, is capped at both ends by the **epiphyses**, and that these are separated from the diaphysis by an epiphyseal plate, which is cartilaginous.

**PHYSICAL FEATURES AND PROPERTIES.** Bone is a hard, mineralized tissue which is slightly elastic and resilient and at the same time relatively light in weight for its volume. With the exception of the enamel and dentin in the teeth, bone is the hardest structure in the body. It withstands tension and compression to a remarkable degree, but can readily be fractured by forces applied suddenly or when it becomes demineralized because of metabolic illness or aging.

Fully grown, mature healthy bone is composed of two kinds of osseous tissue. One is dense in texture, like ivory, and is termed **compact bone**. The other consists of slender spicules called *trabeculae*, which are joined into a spongy structure; because of its resemblance to latticework, this structure is called **cancellous** or **spongy bone**. The compact bone is always located on the exterior, surrounding the cancellous in the interior of the bone. The relative quantity of these two kinds of tissue varies in different bones and in different parts of the same bone, according to functional requirements. Examination

of compact bone with a hand lens shows it to be porous, so that the difference in structure between it and the cancellous bone depends principally upon the relative amount of solid matter, and the size and number of spaces in each. The cavities are small in compact bone and the solid matter between them abundant, while in the cancellous bone the spaces are large and the solid matter is in smaller quantity (Fig. 4-257). The flat tabular bones of the skull are composed of two plates of compact bone, called outer and inner tables, between which is a narrow space of spongy bone called the *diploë*.

**PERIOSTEUM.** The periosteum (Fig. 4-257) adheres to the surface of the bone in every part except the cartilaginous extremities. When strong tendons or ligaments are attached to a bone, the periosteum becomes blended with them. The periosteum consists of two closely united layers. The outer layer is formed chiefly of collagenous tissue, containing occasionally a few fat cells. The inner layer, which can itself be separated into thinner layers, is formed of fine elastic fibers composing dense membranous networks. During life bone is permeated by blood vessels, which course through the periosteum to achieve hard tissue. If the periosteum is stripped from the surface of living bone, small bleeding points mark the paths of periosteal vessels. In young bones the periosteum is thick and exceedingly vascular and is intimately connected at both ends of the bone with the epiphyseal cartilages, but less closely with the shaft of the bone, from which it is separated by a layer of soft tissue containing a number of bone-forming cells, the **osteoblasts**. These cells are responsible for the process of ossification on the exterior of the young bone. Later in life the periosteum is thinner and less vascular, and the osteoblasts are converted into an epithelioid layer of resting osteoprogenitor cells, which remain in contact with the surface of the bone. If a bone is injured, these cells become active bone-forming elements, assisting in regeneration and repair. Because of the rich distribution of periosteal vessels to the underlying bone, it is understandable why bone denuded of its periosteal layer is more subject to exfoliation and necrosis. In summary, it should be emphasized that although the superficial outer fibrous layer of periosteum acts as a limiting membrane upon which muscles, tendons, and ligaments can

**Fig. 4-257.** Portion of finger bone from which marrow has been removed to show spongy bone. 10  $\times$ .

attach, the inner layer is a more dynamic and functionally oriented tissue, interfacing with the underlying bone and assisting in the support of its metabolic processes. Fine nerves and lymphatics, which generally accompany the arteries, may also be demonstrated in the periosteum.

**BONE MARROW.** Bone marrow is the soft, fatty tissue found in the medullary cavities of bones as well as in their cancellous extremities. Bone marrow is widely dispersed and two types exist, yellow and red. **Yellow marrow** is found in the large cavities of the long bones. It consists for the most part of fat cells and a few primitive blood cells, but it may be replaced by red marrow in anemia. **Red marrow** is a hemopoietic tissue and is an important site for the production of granular leukocytes (neutrophil, eosinophil, and basophil leukocytes) and red blood cells (erythrocytes). It is found in the flat and short bones, the articular ends of the long bones, the bodies of the vertebrae, the cranial diploë, and the sternum and ribs. Red marrow consists, for the most part, of mye-

loid cells, which are primitive blood cells in immature stages. Macrophages, fat cells, and megakaryocytes (giant cells) are also always present. Both types of marrow consist of a framework of reticular connective tissue fibers through which course fine vascular sinusoids which are derived from the nutrient vessels of the bone. The sinusoids are lined with phagocytic elements, and the myeloid cells are arranged in cord-like rows outside the sinusoids. The newly formed blood cells are able to gain access to the sinusoids and thereby great numbers of recently matured blood cells (both red and white) pass into the blood stream. The mechanism whereby the mature cells enter the blood stream and immature ones are held back is not known. The maturation of the various blood cell types from the more primitive undifferentiated elements is a subject that is still unclear. Most accounts invoke a pluripotential cell type or **stem cell** which then differentiates into the precursor cells of the different myeloid elements. Additional research is also required to explain the various meta-

bolic influences that hormones and other systems in the body have on the process of hemopoiesis.

**VESSELS AND NERVES OF BONE.** The **arterial blood vessels** that supply bone are numerous. Three sources of blood to bone are usually identified: (1) a limited supply is derived from the **periosteal arteries**, (2) the majority of blood comes from the **nutrient artery**, and (3) in long bones, a significant supply comes from the **epiphyseal arteries**. Because the periosteum contains a dense network of vessels ramifying its structure, at one time it was thought that most of the blood supply to the cortex of a bone came from the periosteal vessels and filtered into the Haversian canals from these peripheral sites. Recent studies, however, have shown that the circulation to at least two-thirds of the cortex comes from the other direction by way of the nutrient artery. However, it does appear that at a few sites, periosteal arteries supply more significant amounts of blood to the cortex. Additionally, if the nutrient artery is injured, the cortex is then supplied principally from periosteal vessels by way of anastomosing channels. The *nutrient artery* enters the shaft of a bone through a foramen in the compact layer. It then branches into longitudinally oriented vessels, which supply the bone marrow and spongy tissue as far as the epiphyseal plates. A single nutrient artery may exist as in the tibia, but there may be several as in the femur. The nutrient artery is usually accompanied by one or two veins. The ends of long bones are supplied by **metaphyseal** and **epiphyseal arteries**. These epiphyseal vessels pass into the marrow cavities of the epiphyses, and they, along with the metaphyseal arteries, anastomose in the region of the epiphyseal plate with fine branches from the nutrient artery.

The **venous blood vessels** that drain bone are quite comparable anatomically to the arteries that supply it. In long bones these emerge in three places: (1) one or two **nutrient veins** accompany the artery; (2) numerous large and small veins emerge at the articular extremities as **epiphyseal veins**, and (3) many small veins pass out of the compact substance as **periosteal veins**. It appears that the periosteal veins drain a greater percentage of blood than once was thought, and the nutrient veins drain less. Thus, the drainage pattern is physiologically different from the arterial supply, even though anatomically

comparable vessels are found. In the flat cranial bones the veins are large, very numerous, and run in tortuous canals in the diploic tissue. The sides of these canals are formed by thin lamellae of bone which are perforated, allowing the passage of adjacent veins. This pattern is similar to that seen in other cancellous tissue—finely coated veins being enclosed and supported by osseous material. When a bone is divided, the vessels remain patent, and do not contract in the canal in which they are contained.

**Lymphatic vessels** can be identified in the periosteal covering of bone accompanying the periosteal vessels, but are much more difficult to demonstrate in bone tissue itself. There have been claims, however, of their existence in the Haversian canals.

**Nerve fibers** are distributed freely to the periosteum, and accompany blood vessels into the interior of the bone. They appear to be most numerous in the articular extremities of the long bones, in the vertebrae, and in the larger flat bones. Both myelinated and unmyelinated fibers have been demonstrated, and it is probable that they are not only vasomotor but sensory in function.

#### MICROSCOPIC STRUCTURE OF BONE

A transverse slice of compact bone may be further ground until it is sufficiently thin to be examined under the light microscope. At low magnification, the bone will be seen to be mapped out into a number of circular units, each consisting of a central opening surrounded by a number of concentric rings (Fig. 4-258). These units are termed **Haversian systems**, and the central opening is an **Haversian canal**. The rings are layers of bony tissue arranged concentrically around the central canal, and termed **lamellae**. Moreover, on closer examination it is found that between these lamellae, and therefore also arranged concentrically around the central canal, are a number of small spaces, the **lacunae**, and that these lacunae are connected with each other and with the central Haversian canal by many fine channels, which radiate like the spokes of a wheel and are called **canaliculi** (Fig. 4-259). Within the lacunae are the cell bodies of the bone cells, or **osteocytes**, and the canaliculi contain the cytoplasmic processes of the osteocytes. Between the more regularly oriented circular (in transverse section) Haversian systems are

**FIG. 4-258.** Transverse section of compact dried bone taken from the diaphysis of the tibia. Observe that bone consists of lamellae arranged in concentric layers which form the Haversian systems and between these systems are the interstitial lamellae. Inner and outer circumferential lamellae form the surface layers of bone. Stain: Aniline blue. 80  $\times$ . (From di Fiore, *Atlas of Human Histology*, Lea & Febiger, Philadelphia, 1981.)

**FIG. 4-259.** Cross section of an Haversian system showing its central canal, the lacunae which contain cell bodies of osteocytes and the intercommunicating canaliculi. Specimen is from human femur. (From Greep and Weiss, *Histology*, 3rd Edition, McGraw-Hill, New York, 1973.)

irregularly shaped bony intervals, which also contain lacunae and canaliculi filled with osteocytes and their processes. These are called the **interstitial systems**, and they also reveal a lamellar structure created by the more or less curved **interstitial lamellae**. Additionally, other lamellae are found on the surface of the bone and are arranged parallel to its circumference. They are termed **circumferential**, or **primary lamellae**, to distinguish them from those surrounding the axes of the Haversian canals, which may then be termed **secondary lamellae** (Fig. 4-258).

**HAVERSIAN CANALS.** The Haversian canals, which in cross section are observed as openings in the center of each Haversian system, appear as true canals in a longitudinal section (Fig. 4-260). The canals course parallel with the longitudinal axis of the bone for a short distance. The Haversian canals communicate with each other and with the surfaces of the bone by oblique or transversely crossing channels called **Volkman's canals**. Haversian canals vary considerably in size, some measuring as much as 0.12 mm in diameter, but their average diameter is about 0.05 mm. The canals nearer the medullary cavity are larger than those closer to the surface of the bone. Each canal contains one or two small blood vessels surrounded by a small quantity of delicate connective tissue and some nerve filaments. Those Haversian canals near the surface of the bone open upon it by minute orifices, and those near

the medullary cavity similarly open into this space. Thus, it can be appreciated that the entire bone is permeated by a system of blood vessels that course through the bony canals in the centers of the Haversian systems. The blood vessels branch and course through the Volkmann canals, thereby forming an interconnecting vascular network.

**BONY LAMELLAE.** One of the most characteristic features of bone is its layered structure. These layers, or **lamellae**, are thin plates of bone tissue arranged around a central hollow cylinder called the Haversian canal. The lamellae are composed of collagenous bundles arranged in a parallel direction within each layer. The bundles of collagen in adjacent lamellae, however, are oriented in different directions. It does not appear that a simple perpendicular arrangement of collagen bundles exists in adjacent layers. Instead it is believed that the collagen fibers are arranged in a helical manner in each layer, and that the pitch of the helix changes in bundles of adjacent layers. Nonetheless, in a cross section of stained decalcified bone, lamellae with bundles cut longitudinally appear striated, and these alternate with lamellae in which the bundles of fibers are cut transversely, giving a more punctate appearance. In addition to the **Haversian system lamellae**, bones contain **interstitial lamellae** occupying the spaces between the Haversian systems, as well as the **outer** and **inner circumferential lamellae**, which form an external encasement of a bone as well as

**FIG. 4-260.** Longitudinal section of compact bone tissue. Note that the Haversian canals communicate with each other by means of transverse channels called Volkmann's canals.

the bony layers lying subjacent to the endosteal lining in the central core of a bone. In all these sites the microanatomy of the lamellae is similar. Between the bundles of collagenous fibers and between the lamellae are found a darker staining amorphous extracellular substance containing deposits of calcareous salts. In many places the lamellae appear to be pinned together by **perforating fibers**, which run obliquely through them. Similar fibers, called **Sharpey's fibers**, extend from the surface of a bone into the substance of the periosteum, anchoring the latter to the bone. These perforating fibers may be demonstrated in the dissecting room by detaching the scalp from the calvaria,

which then is covered by fine projections (Sharpey's fibers) as well as coarser projections containing minute blood vessels.

**LACUNAE AND CANALICULI.** The **lacunae** are oblong spaces situated between the lamellae. In a microscopic section of dried bone, viewed by transmitted light, lacunae appear as fusiform opaque spots. Each lacuna is occupied during life by a bone cell or **osteocyte**, processes of which extend into the **canaliculi**, which are exceedingly minute channels that cross the lamellae and connect the lacunae with neighboring lacunae and also with the Haversian canal (Fig. 4-259). In the center of an Haversian system, a number of canaliculi radiate from the Haversian

**FIG. 4-261.** Two osteoblasts, with nuclei identified N1 and N2, are located above and to the left and in the lower part of this electron micrograph. The cells lie adjacent to a mass of fully calcified bone B, which then continues to the left as more recently deposited incompletely calcified preosseous matrix. Observe the profuse amount of endoplasmic reticulum in the cytoplasm of the osteoblasts along with a prominent Golgi complex, G. Arrows point to processes of osteoblasts which extend into the area of bone calcification. 9200  $\times$ . (From Hancox, N.M., *Biology of Bone*, Cambridge University Press, London, 1972.)

**FIG. 4-262.** An osteocyte within a lacuna surrounded by fully developed bone. Note that the endoplasmic reticulum is sparse and the Golgi complex not well developed. Arrows point to irregularities on the cell surface which are sites of extensions of osteocyte processes destined toward the canaliculi. The lacunar wall in this specimen is not fully mineralized. 10,000  $\times$ . (From Cameron, D.A. in *The Biochemistry and Physiology of Bone*, Vol. 1, ed. G.H. Bourne, Academic Press, New York, 1972.)

canal and open into the first set of lacunae between the first and second lamellae. From these lacunae a second set of canaliculi proceed to the next series of lacunae, and so on until the periphery of the Haversian system is reached. The canaliculi radiating from the most peripheral series of lacunae do not as a rule communicate with the lacunae of neighboring Haversian systems, but after passing outward for a short distance, they form loops and return to their own lacunae. Thus, every part of an Haversian system is supplied with nutrient fluids derived from the vessels in the Haversian canal and distributed through the canaliculi and lacunae.

**CELLS OF BONE.** The cellular elements in bone are distinguishable as probably four functional variants in the same cellular lineage. Bone cells transform from **osteoprogenitor cells** to **osteoblasts**, which then become **osteocytes**, the principal cells of adult bone. **Osteoclasts**, which are responsible for bone resorption, constitute the fourth cell

variant in bone. Although their origin is not certain, it is felt that osteoclasts, which are giant multinucleated cells, arise from the coalescence of many mononuclear osteoprogenitor cells.

Like all other cells in connective tissue, bone cells develop from the mesenchyme. **Osteoprogenitor cells** are relatively undifferentiated cells which line the inner aspect of the periosteum as well as help to form the endosteal lining of the inner bone cavity. These cells also line the Haversian canals. Osteoprogenitor cells undergo mitosis and can be transformed into osteoblasts or they can coalesce to form osteoclasts. They are flat cells and lie directly on the surface of bone. They have oval nuclei and a relatively scanty cytoplasm.

**Osteoblasts** are bone-forming cells and therefore are always found at the interface between bone and cartilage in developing or growing bone or at the site of repair in an injured bone. During an active phase, these

**FIG. 4-263.** A portion of an osteoclast including part of a nucleus, several Golgi elements and mitochondria. Observe in the lower part of the micrograph the ruffled border of the osteoclast closely applied to an area of bony matrix which is being resorbed. (From Bloom and Fawcett, *A Textbook of Histology*, W. B. Saunders Co., Philadelphia, 1975. Electron micrography by Dr. P. R. Garant.)

cells appear as a layer of low columnar cells and they assume an epithelial-like structure. Osteoblasts are active secretory cells, and therefore it is not surprising that electron microscopic studies have revealed their extensive rough endoplasmic reticulum and prominent Golgi complex (Fig. 4-261). Both cytoplasm and nucleus of the osteoblasts are intensely basophilic. Upon completion of bone growth or bone regeneration, osteoblasts become surrounded by the matrix they secrete and become encased in lacunae, thereby assuming the characteristics of osteocytes.

**Osteocytes** are the principal cells found in fully developed bone. They occupy the lacunae and their processes pass into the surrounding canaliculi. With the light microscope only the nucleus is easily discernible with the lacuna. They vary in size, being somewhat larger in younger bone than older. With the electron microscope it has been shown that the processes of adjacent osteocytes form contacts with each other, an indication of their functional interrelationship rather than an isolated action. Osteocytes have a more limited amount of rough endoplasmic reticulum than do osteoblasts (Fig. 4-262), and it is believed that they participate in the passage of calcium from blood to bone. They apparently respond to circulating parathyroid hormone, which induces an increased removal of calcium from bone in a process that has been called osteolysis.

**Osteoclasts** are giant multinucleated cells that appear to be actively involved in the process of bone resorption. They are generally found in shallow spaces called **Howship's lacunae**. Osteoclasts possess finger-like infolded extensions of the cytoplasm adjacent to the bone surface being resorbed, forming what has been termed their fluffy or ruffled border (Fig. 4-263). The portion of the cell away from the ruffled border is more apt to

contain the many nuclei of the cell. The cytoplasm near the nuclei also contains multiple Golgi complexes. The manner by which these cells resorb bone is still unclear, but it is believed that they can secrete hydrolytic enzymes that are capable of disintegrating and digesting bone.

**CHEMICAL COMPOSITION OF BONE.** Bone consists of an organic and an inorganic part intimately combined.

The organic part may be isolated by immersing a bone for a considerable time in dilute mineral acid, after which the bone retains its original shape but becomes completely flexible. This flexibility may be demonstrated, for example, by a long bone such as a rib, which can easily be tied into a knot after it has been demineralized. If then a transverse section is made, the same general arrangement of the Haversian canals, lamellae, lacunae, and canaliculi is seen. The organic part of bone consists of the cells, the collagen fibers, and the amorphous ground substance which contains glycoproteins.

The inorganic part may be separately obtained by calcination, a process by which all the organic constituents are completely burnt away. The bone will still retain its original form, but it will be white and brittle, will have lost about one-third of its original weight, and will crumble with the slightest force. The structure of the principal mineral in bone is most closely similar to the substance *hydroxyapatite*. This is a form of calcium phosphate, but bone also contains carbonate and citrate ions as well. Elements such as fluoride, strontium, and isotopes of calcium and phosphorus can be substituted into the chemical makeup of bone mineral. The crystals of mineral are extremely small but may be visualized with the electron microscope. The inorganic part confers to bone its hardness and rigidity, while the organic part gives bone its resilience and tenacity.

## The Joints

Articulations, or joints, are specialized anatomical structures at which the ends of certain bones are joined or the borders of other bones juxtaposed. These osseous junctions are secured by ligaments, fibrous capsules, and other binding tissues which restrict movement or permit varying degrees of movement. Joints vary widely in their structure, frequently presenting unique morphological features adapted to specific functional requirements.

The study of joints is called **arthrology**, and it is initially of practical importance for the student to realize that movement does not occur in all joints. In *immovable* articulations, the bones are held together by several fibrous layers. These joints are called sutures and they are peculiar to the skull. The adjacent margins of the skull bones are serrated and interlocked, being separated merely by the thin, fibrous sutural ligament. In certain regions at the base of the skull this fibrous membrane is replaced by a layer of cartilage. These are **joints adapted for growth** of the brain. In the developing and maturing infant the brain is enclosed by a membrane destined to ossify. The membranes of the cranial bones are in contact peripherally and ossify from more central-

ized sites. After the completion of brain growth, the sutures close and become unyielding, thereby forming the rigid cranial vault. A comparable, but not identical, situation exists in many limb bones between the ossifying epiphyses and diaphyses. These junctions, temporarily cartilaginous, become ossified after allowing full growth of the maturing limb.

In contrast to joints adapted for growth are **joints adapted for movement**. At certain joints slight movement combined with great strength is required. In most of these articulations the osseous surfaces are united by tough and flexible fibrocartilages as in the joints between the vertebral bodies, and in the interpubic articulation. In the *freely movable* joints the bony surfaces are completely separated, and the ends of the bones are expanded or so contoured as to facilitate the connection. Additionally, the osseous surfaces are covered by cartilage and enveloped by capsules of fibrous tissue. The cells lining the interior of the fibrous capsule form the synovial membrane which secretes a lubricating fluid. The joints are strengthened by strong fibrous bands, the ligaments, which extend between the bones.

### Development of the Joints

The development of the joints naturally is related to the development of the skeletal elements that they interconnect. Because the skeleton forms from mesoderm, it follows that the tissues forming the joints are also derived from this germ layer. The development of the intervertebral joints occurs simultaneously with the development of the vertebrae. As discussed in Chapter 4, these bones form from a column of mesoderm which becomes divided into sclerotomes along the central axis of the embryo. The intervertebral discs, which become interposed between the vertebral bodies, also form from the sclerotomes. From the sides of the embryo, limb buds develop at the end of the fourth week, and shortly after their appearance, central cores of mesoderm form continuous axes throughout their length. At first the mesoderm from which the different parts of the skeleton will form shows no differentiation between the masses that will correspond to the individual bones. During the fifth week, however, circumscribed conden-

sations of mesenchyme appear within the mesodermal core of the limb bud and present the first indications of the bones of the limbs. Within these condensations of mesenchyme, chondrogenic centers appear, one for each future bone. The mesenchyme intervening between the chondrifying skeletal elements is initially a homogeneous undifferentiated region called the **interzone** (Fig. 5-1,A).

The manner in which the interzone mesenchyme develops further into a joint depends on the type of joint being formed. The mesenchyme may be converted into white fibrous tissue, as in the case of the skull bones, a **fibrous joint** being the result. In contrast, it may form hyaline cartilage or fibrocartilage, in which case a slightly movable **cartilaginous joint** is formed. The interzone of a developing, freely movable, **synovial joint** consists of three layers, two of which are chondrogenic, each continuous with the perichondrium and capping the ends of the developing cartilage. Between these two layers is an intermediate loose layer of mesenchyme (Fig. 5-1,B). Surrounding the interzone are layers of condensing mesenchyme, which become the **articular fibrous capsule**, and interposed between the interzone and the capsule is the synovial mesenchyme. During the sixth week small cavities appear in the intermediate mesenchyme layer of the interzone and in the synovial mesenchyme (Fig. 5-1,C). As these cavities coalesce, the joint cavity is formed. On the inner surface of the fibrous capsule, the mesenchymal cells differentiate into a mesothelial lining, forming the **synovial membrane** (Fig. 5-1,D).

The tissue surrounding the original mesodermal core forms the perichondrial and periosteal fibrous sheaths for the developing bones. These sheaths are continuous with the articular fibrous capsule which overlies the synovial membrane and encases the joint cavity. All parts of a joint capsule are not of uniform thickness, so that in them may be recognized especially strengthened bands, which become ligaments. Additional ligamentous bands are at times formed by remnants of tendons surrounding the joint.

In several of the movable joints the intermediate layer mesenchyme of the interzone between the ends of the bones does not become completely absorbed, but persists to form fibrous or cartilaginous elements. Some

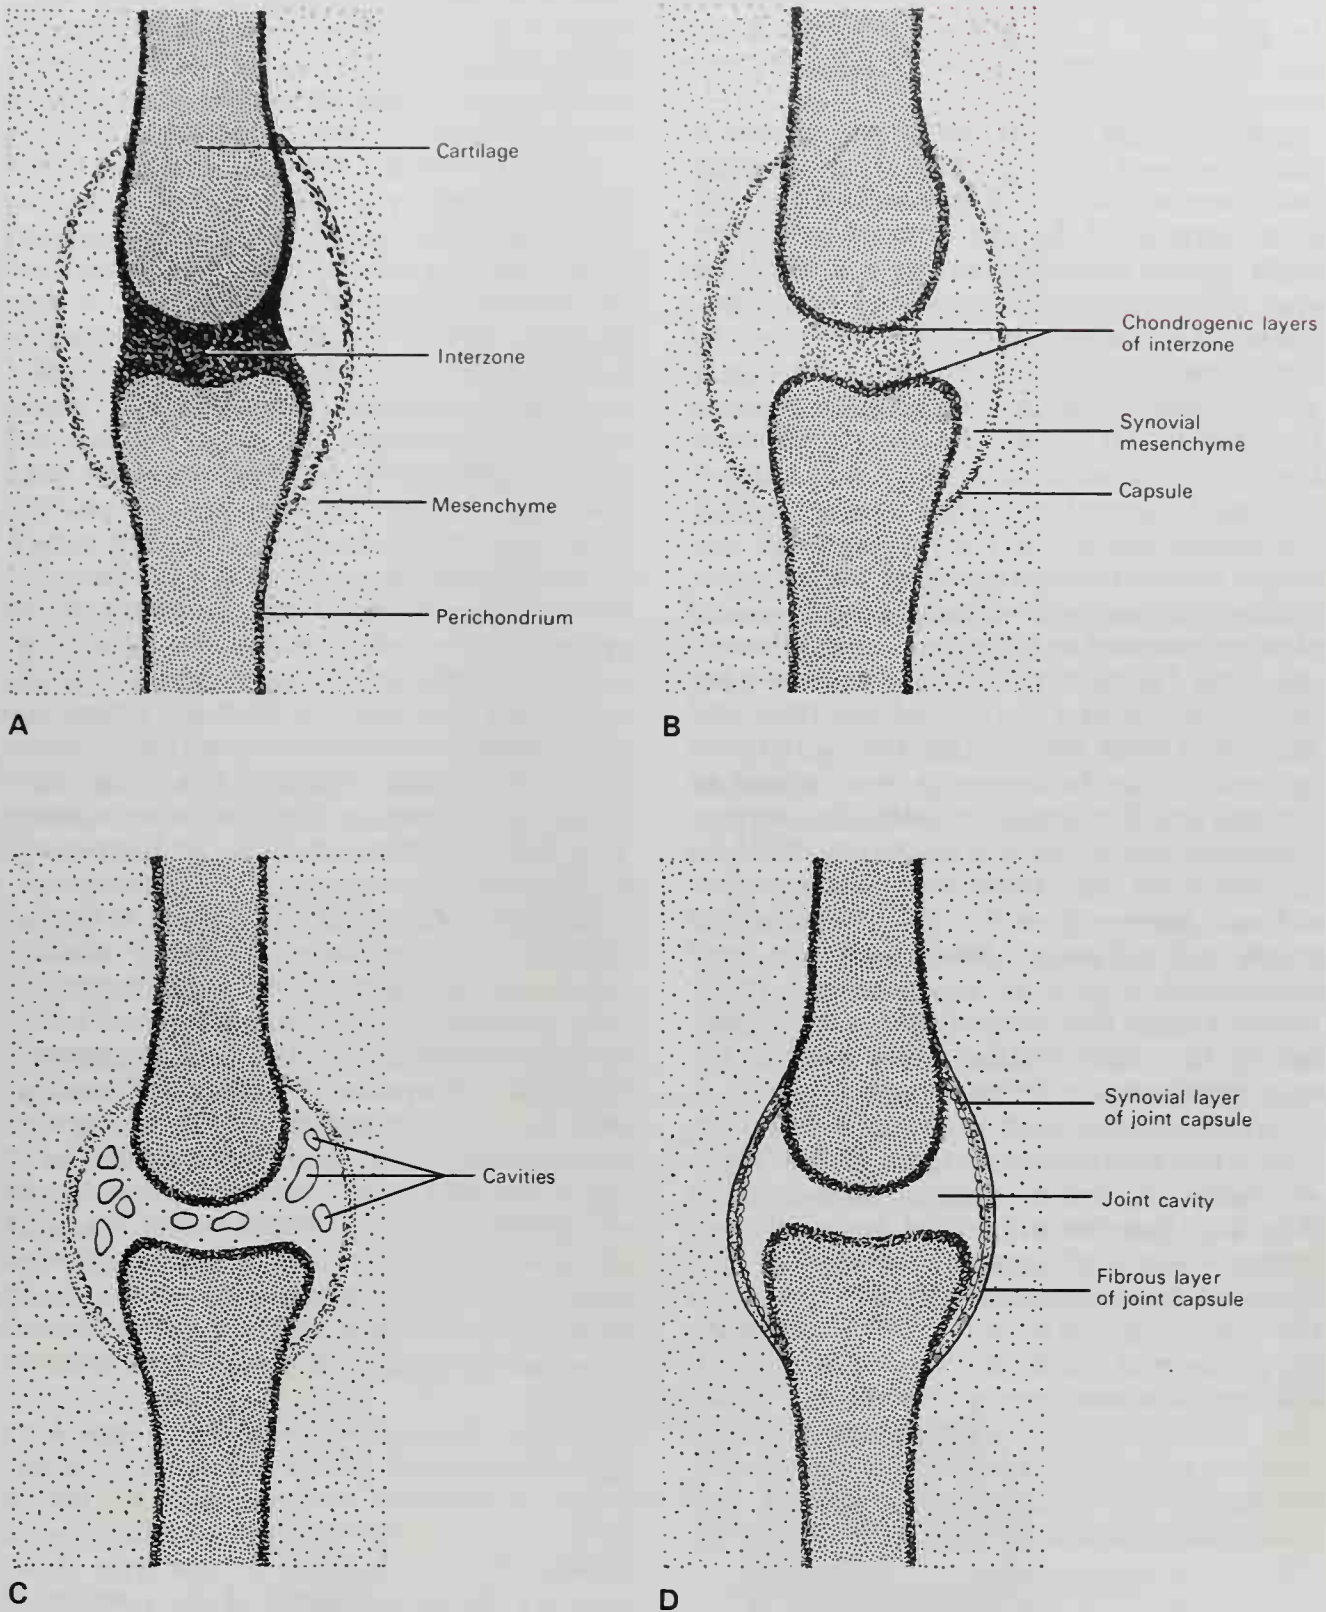

of these elements, such as the menisci of the knee joint or the temporomandibular joint, become intimately associated in their development with the muscles surrounding the joint. Other cartilaginous structures, such as the articular disc of the sternoclavicular joint, significantly strengthen the articulation, intervening between the ends of the bones in such a manner as to form two joint cavities.

## Classification of Joints

It has already been mentioned that joints may be classified according to those *adapted for growth* and those *adapted for movement*. The former are immovable joints, while among the latter are included the slightly movable and freely movable joints. Although all joints can be listed within these two functional categories, little information about the anatomical nature of the joints is conveyed by such a classification. Because of the uniqueness of many articulations, however, no completely adequate classification scheme has been devised that covers the many individual differences among the joints. Perhaps the most frequently utilized classification system, and one officially recognized by the *Nomina Anatomica*, is dependent strictly on the morphological characteristics of the joints. This schema recognizes that principally three types of tissue separate the ends of bones in the different joints: fibrous tissue, cartilage, or synovial membranes. Thus, it distinguishes: (1) **fibrous joints** (many of which are immovable; *synarthroses*); (2) **cartilaginous joints** (slightly movable; *amphiarthroses*); and (3) **synovial joints** (freely movable; *diarthroses*).

### FIBROUS JOINTS

The fibrous joints include all those articulations in which the surfaces of the bones are nearly in direct contact, and in which the adjoining bones are fastened together by fibrous connective tissue. There are three varieties of fibrous joints: **syndesmoses**, **sutures**, and **gomphoses**. In many of these joints there is no appreciable movement, as in those articulations between the bones of the skull which form the cranial vault. How-

**FIG. 5-1.** Schematic diagrams showing the developmental stages of a synovial joint. In A, the cartilaginous models of the developing bone are separated by a homogeneous region, the interzone. As shown in B, the interzone soon becomes transformed into two chondrogenic layers continuous with the perichondrium and separated by an intermediate layer of mesenchyme. Condensation of the mesenchyme laterally forms a primitive joint capsule within which small cavities appear, C, and then coalesce, D, to form the joint cavity, while the articular capsule differentiates into an inner synovial layer and an outer fibrous layer. (Modified from Langman, J., *Medical Embryology*, Williams and Wilkins, 1963.)

ever, very limited movement is permitted in syndesmoses (such as the inferior tibiofibular joint) and in the gomphoses (which are the joints between the roots of the teeth and their bony sockets).

**SYNDESMOSES.** A syndesmosis is usually described as a type of articulation in which two bones are joined by an interosseous ligament formed of fibrous connective tissue. Such a joint generally allows a limited degree of movement. Examples of syndesmoses are the inferior tibiofibular joint and the articulation between the base of the stapes and the margin of the vestibular window in the middle ear. More broadly considered, the syndesmoses could include any number of slightly movable skeletal unions which are interconnected by fibrous ligaments and which do not contain synovial sacs or intervening cartilaginous discs. Thus, it would also be reasonable to include as syndesmoses such ligamentous unions as those between the parallel borders of the tibia and fibula and those between the radius and ulna formed by the interosseous membranes of the leg and forearm. Similarly, the coracoclavicular union, as well as others, could be regarded as syndesmoses. These latter unions, however, were not classified as joints in the *Nomina Anatomica*, but were considered simply as ligamentous attachments. Under this exceedingly narrow definition, the inferior tibiofibular joint is the only syndesmosis in the human body.

**SUTURES.** A suture is an articulation in which the contiguous margins of the bones are united by a thin layer of fibrous tissue (Fig. 5-2). Sutures are found only between bones in the skull (cranial and facial). The fibrous sutural ligament interposed between the bony edges derives from the nonossifying portions of the membranes within which the cranial bones develop. It should be noted that after maturation, active bone deposition, or synostosis, partially or completely obliterates the sutural line, a process that continues with aging. Study of the histologi-

FIG. 5-2. Vertical section through the sagittal suture.

cal structure of sutures has shown that each apposing periosteal edge is formed by a layer of osteogenic cells overlaid by fibrous tissue. Between the two periosteal fibrous coverings is a looser vascularized fibrous tissue (Pritchard, Scott, and Girgis, 1956).

In certain sutures the margins of the bones are connected by a series of indented processes which are interlocked. Three varieties of interlocking sutures can be distinguished: denticulated, serrated, and limbous. A **denticulate suture**, as its name implies, is formed by a consecutive series of tooth-like, projecting processes from each side, which frequently measure 5 mm or more, and which interconnect securely across the joint. The sagittal suture between the two parietal bones is an example of a denticulate suture. In a **serrate suture**, as between the two portions of the frontal bone, the edges of the apposing bones show somewhat more regular and shorter projections, resembling the teeth of a fine saw. A **limbous suture** not only presents interlocking serrated edges, but also a certain degree of bevelling of the articular surfaces, so that the bones overlap, as in the coronal suture between the parietal and frontal bones.

In other sutures the articulation is formed by the rough surfaces of bones without serrated edges, which are placed in apposition to one another. There are two types of these nonindented sutures, called squamous and plane. A **squamous suture** is characterized by an overlapping of the contiguous bones along broad bevelled margins, as in the squamosal suture between the temporal and parietal bones. A **plane suture** is simply an apposition of contiguous rough surfaces, which are neither bevelled nor indented, as in the articulation between the maxillae, or between the horizontal plates of the palatine bones.

Finally, the term **schindylesis** is used for a type of suture in which a thin plate of one bone is received into a cleft or fissure formed by the separation of two laminae in another bone. Examples of this type of suture are the articulations of the rostrum of the sphenoid bone and the perpendicular plate of the ethmoid bone with the vomer. Also, the reception of the vomer in the fissures between the maxillae and between the palatine bones is considered a schindylesis.

**GOMPHOSES.** A gomphosis is an articulation that results from the insertion of a coni-

cal process into a socket. This more specialized type of articulation does not occur between bones, strictly speaking, but is seen in the fibrous union of the roots of the teeth with the alveoli of the mandible and maxilla.

### CARTILAGINOUS JOINTS

In a cartilaginous joint the bones are united either by a plate of hyaline cartilage or by a fibrocartilaginous disc. There are two varieties: **synchondroses** and **symphyses**.

**SYNCHONDROSES.** A typical synchondrosis is a temporary form of joint (Fig. 5-3), for the intervening hyaline cartilage is converted into bone before adult life. Such joints are found between the epiphyses and diaphyses of long bones, between the occipital and the sphenoid bones at birth and for some years after, and between the petrous portion of the temporal bone and the jugular process of the occipital bone. Still another example of a synchondrosis is the Y-shaped union of the ilium, ischium, and pubis that forms the cup of the acetabulum.

**SYMPHYSES.** A symphysis is the union of two contiguous bony surfaces connected by a broad, flattened disc of fibrocartilage, as in the articulations between the bodies of the vertebrae or the two pubic bones (Fig. 5-4). Frequently, the fibrocartilaginous disc is separated from the bone by thin layers of hyaline cartilage. Although limited movement occurs at a symphysis, it appears to depend on the thickness of the fibrocartilaginous disc as well as on its degree of elasticity. The slight movements that occur between the bodies of the vertebrae result in the flexibility of the vertebral column. Mobility of the interpubic joint is also of some importance in parturition. The anatomical structure of intervening discs can vary quite widely in different symphyses. An intervertebral disc contains a soft gelatinous center,

Fig. 5-3. Section through occipitosphenoid synchondrosis of an infant.

Fig. 5-4. Diagrammatic section of a symphysis.

called the nucleus pulposus, which lends resilience to the joint. In contrast, the interpubic joint sometimes contains a small fluid-filled cavity. Another symphysis in the body is the manubriosternal joint.

### SYNOVIAL JOINTS

Synovial joints are highly evolved articulations which permit free movement. Because the human lower limbs are concerned with locomotion and the upper limbs provide a great versatility of movement, it is not surprising that most of the joints in the extremities are of the synovial type. In contrast to fibrous and cartilaginous joints where the ends of the bones are bound in continuity with intervening tissue, the ends of the bones in a synovial joint are in contact, but separate. Because the bones are not bound internally, the integrity of a synovial joint results from its ligaments and capsule, which bind the articulation externally, and to some extent from the surrounding muscles. The contiguous bony surfaces are covered with hyaline cartilage, and the joint cavity is surrounded by a fibrous capsule, the inner surface of which is lined by a synovial layer containing cells that are thought to secrete the viscous lubricating **synovial fluid** (Fig. 5-5).

Fig. 5-5. Diagrammatic section of a synovial (diarthrodial) joint. The black area represents the joint cavity.

In certain synovial joints, the joint or **synovial cavity** may be divided, completely or incompletely, by an **articular disc** or **meniscus** (Fig. 5-6). Such discs are fibrocartilaginous, but unlike those seen in cartilaginous joints, intra-articular discs of synovial joints are not connected to the ends of the bones, but are continuous at their periphery with the fibrous capsule. The nonarticular surfaces of such a disc are covered by the synovial membrane, and thus when the joint is completely divided by a disc, as is the temporomandibular joint, two joint cavities are found within the fibrous capsule. Synovial joints involving two bones and containing a single joint cavity are sometimes referred to as **simple joints**; joints that contain an articular disc, thereby forming two joint cavities, are called **composite joints**. The term **compound joint** is used for those articulations in which more than a single pair of articulating surfaces are present.

The varieties of synovial joints have been classified by the types of active motion that they permit (uniaxial, biaxial, and polyaxial), but are differentiated further according to their principal morphological features (hinge, pivot, condyloid). In some joints the movement is **uniaxial**, that is to say, all movements take place around one axis. Among these are the **ginglymus** or hinge joint, in which the axis of movement is, for all practical purposes, transverse to the axes of the bones, and the **trochoid** or pivot joint, in which the axis is longitudinal. In other varieties the movements are **biaxial**, or around two axes at a right angle or any other angle to each other. These include the **condyloid**, the **ellipsoid**, and the **saddle joints**. There is one type of joint in which the move-

ments are **polyaxial**, the **spheroidal** or ball-and-socket joint, at which movements are permitted in an infinite number of axes. Finally, there are the **plane** or gliding joints.

**GINGLYMUS OR HINGE JOINT.** The articular surfaces of a ginglymus joint are molded to each other in such a manner as to permit motion in only one plane, around the transverse axis. Although these joints are uniaxial, they frequently permit a considerable degree of motion. Flexion at the elbow joint, for example, can reduce the angle between the forearm and arm from about  $180^\circ$  to less than  $45^\circ$  in the fully flexed position. The direction that the distal bone takes in this motion is seldom in exactly the same plane as that of the axis of the proximal bone, because there is frequently a certain deviation from the straight line during flexion. The bones of a hinge joint are usually connected by strong collateral ligaments, which form their chief bond of union. In addition to the elbow joint, other examples of ginglymus joints include the **interphalangeal joints** of both the fingers and toes.

**TROCHOID OR PIVOT JOINT.** Movement in a trochoid or pivot joint also occurs around a single axis, which in these joints is the longitudinal axis. Trochoid joints are formed by a bony pivot-like process surrounded by a ligamentous ring, which may also be partly bony. Movement of the joint occurs as the pivot turns within the ring, or as the ring turns around the pivot, in both instances around the longitudinal axis. There are several pivot joints in the human body. In the **proximal radioulnar articulation**, the ring is formed by the radial notch of the ulna and the annular ligament. The head of the radius forms the pivot, which rotates within the ring. In the **articulation of the dens of the axis with the atlas**, the ring is formed in front by the anterior arch of the atlas, and posteriorly by the transverse ligament of the atlas. In this joint the ring turns around the bony pivot or dens. The distal radioulnar joint is also of the trochoid type.

**CONDYLAR JOINT.** In a condylar joint movement occurs principally in one plane, and although a slight degree of rotation can also occur at an axis at right angles to that of the principal movement, the rotation is severely limited by the disposition of the ligaments and tendons associated with the joint. In these joints, a pair of convex condyles are received in appropriately shaped concavities. The **tibiofemoral articulation** of the

**FIG. 5-6.** Diagrammatic section of a synovial joint with an articular disc. The two black areas represent the joint cavities separated by the disc.

knee joint is an example of the condylar joint.

**ELLIPSOID JOINT.** Ellipsoid joints allow movements around two principal axes which are at right angles to each other. In these joints an oval convexity is received into an elliptical concavity, allowing a flexion-extension mobility as well as abduction-adduction movements. A combination of these movements results in circumduction, but there is little if any rotation around the third axis because of the ellipsoid shape of the articulating surfaces. Examples of ellipsoid joints include, among others, the *radiocarpal* and *metacarpophalangeal* joints.

**SADDLE JOINT.** In saddle (or sellar) joints the articular end of the proximal bone is concave in one axis and convex in a perpendicular axis. These surfaces fit reciprocally into convex and concave surfaces of the distal bone. Movements at such a reciprocally apposed concavoconvex articular surface are the same as in ellipsoid joints, that is, flexion, extension, adduction, abduction, and circumduction are allowed. A modest degree of axial rotation is seen as well, especially in conjunction with the principal movements. The best example of a saddle joint is the *carpometacarpal* joint of the thumb.

**SPHEROID OR BALL-AND-SOCKET JOINT.** A spheroid or ball-and-socket joint is one in which the distal bone is capable of motion around an indefinite number of axes, which have one common center. It is formed by the reception of a globular head into a cup-like cavity; however, the so-called sphere does not have the same diameter in all directions, and hence is slightly ellipsoid in shape. The greater the depth of the socket, the more stable the joint, but a deeper socket also results in more limited movement. Examples of this form of articulation are found in the *hip* and *shoulder* joints.

**PLANE OR GLIDING JOINT.** A plane or gliding joint allows only a slight slipping or sliding of one bone over the other. Such a joint is formed by the apposition of plane surfaces, or of one slightly concave and the other slightly convex surface. The amount of motion between the surfaces is limited by the ligaments or osseous processes that surround the articulation. It is the form present in the joints between the *articular processes of certain vertebrae*, the *carpal joints* (except that of the *capitate* with the *scaphoid* and *lunate*), and the *intermetatarsal* joints.

## Movements at Joints

The movements admissible in joints may be divided into four types: **gliding** and **angular movements**, **circumduction**, and **rotation**. Often, however, these movements are combined in varying degrees within joints to produce an infinite variety, and seldom is only a single type of motion found in any particular joint.

**GLIDING MOVEMENT.** Gliding movement is the simplest type of motion that can take place in a joint, one surface gliding or moving over another without any significant angular or rotatory movement. The gliding movement is frequently combined with other movements at many joints, but in some, as in most of the *intercarpal* and *intermetatarsal* articulations, it is the principal motion permitted. This movement is not confined to plane surfaces, but may exist between any two contiguous bony surfaces, of whatever shape.

**ANGULAR MOVEMENT.** Angular movements increase or decrease the angle between two adjoining bones. Flexion-extension and abduction-adduction are the common examples, each pair of movements acting in different axes which are at right angles.

**Flexion** occurs when the angle between two bones is decreased. A typical example is the bending of the upper extremity at the elbow. In some instances rather arbitrary definitions must be given. For example, bringing the femur forward or ventrally at the hip is flexion, but this motion includes the entire arc beginning in a position with the limb held back and then brought forward, as in kicking an American football, and also includes approximating the thigh against the anterior aspect of the trunk. Flexion at the knee approximates the calf and the posterior thigh, while the term *dorsiflexion* is used for the movement at the ankle joint that attempts to bring the dorsal foot in proximity to the anterior leg. Flexion of the *interphalangeal* joint of the thumb tends to approximate the palmar surfaces of the two segments of that digit, while flexion of the *metacarpophalangeal* joint of the thumb brings that digit across the surface of the palm.

**Extension** occurs when the angle between the bones is increased, as when the forearm is aligned to the arm, and generally is the action opposite flexion. *Hyperextension* is the term used for moving through an arc in

the same direction, but beyond the straight position, as in bringing the arm back before launching a bowling ball. *Plantar flexion* of the foot at the ankle joint is the opposite of dorsiflexion, and by this action an attempt is made to approximate the plantar surface of the foot with the calf.

**Abduction** occurs when a limb is moved away from the midsagittal plane of the body, or when the fingers and toes are moved away from the median longitudinal axis of the hand or foot. An exception is abduction at the carpometacarpal joint of the thumb, where abduction is that action by which the thumb is elevated anterior to the palm.

**Adduction** occurs when a limb is moved toward or beyond the midsagittal plane or when the fingers or toes are moved toward the median longitudinal axis of the hand or foot. Once again the plane of movement of the carpometacarpal joint of the thumb is different. In the anatomical position, adduction carries the abducted thumb in a posterior direction toward the plane of the palm.

**CIRCUMDUCTION.** Circumduction is a form of motion that takes place when the head of a long bone revolves within its cup-like cavity. The bone thereby circumscribes a conical space, the base of which is directed distally, while the apex of the cone is in the articular cavity. Circumduction is a sequence of flexion, abduction, extension, and adduction. This type of movement is best seen at the shoulder and hip joints.

**ROTATION.** Rotation is a form of movement in which a bone moves around a central axis without undergoing any other displacement. A bone may rotate around its own longitudinal axis, as in the rotation of the humerus at the shoulder joint, or alternatively, the central axis of rotation may lie in a separate bone, as in the case of the pivot formed by the dens of the axis around which the atlas turns. The axis of rotation may not even be exactly parallel to the long axis of the bone, as in the movement of the radius on the ulna during pronation and supination of the hand. In this latter instance, the axis of rotation is represented by a line connecting the center of the head of the radius proximally with the center of the head of the ulna distally.

In the anatomical position the upper extremities are oriented along the sides of the trunk with the palms facing anteriorly, or in the **supine** position. If the radius is rotated

diagonally across the ulna and the palm is made to face dorsally, the hand is said to be in the **prone** position. **Supination** and **pronation** of the forearm and hand are those rotatory movements of the radius in the forearm that achieve these alternate positions of the hand.

## Structures of Synovial Joints

**ARTICULAR CARTILAGE.** Firmly adherent to the articular surfaces of a majority of bones is a smooth, glistening and resilient layer of hyaline cartilage. Conforming to the shape of the bony surfaces upon which it rests, **articular cartilage** may vary in thickness from 0.5 mm on smaller bones of older individuals to as much as 6 or 7 mm on long bones during maturation. Normally articular cartilage is not visible roentgenographically and principally accounts for the space between the bones seen in roentgenograms. In a few instances, as in the temporomandibular joint, the articular surfaces are covered by white fibrocartilage. Generally that portion of the articular cartilage adjacent to the bone tends to show calcification. Articular cartilage is neither innervated nor supplied with blood vessels. It probably receives its nourishment both from the synovial fluid and by diffusion from fine vessels that supply the synovial membrane and the adjacent bone, as well as from those that nourish the capsule.

**LIGAMENTS.** Ligaments are composed mainly of bundles of **collagenous fibers** oriented in parallel, or closely interwoven to present a white shining, iridescent appearance. They are pliant and flexible to allow perfect freedom of movement, but they are also strong, tough, and inextensible, so as not to yield readily to applied force. Some ligaments consist entirely of **yellow elastic tissue**, as the ligamenta flava which interconnect the laminae of adjacent vertebrae, and the ligamentum nuchae seen in the dorsal neck of grazing animals. In these latter instances the elasticity of the ligament acts as a substitute for muscular power. Ligaments are frequently distinct anatomical structures, such as the collateral ligaments of the elbow and knee joints. At times, however, ligaments are closely applied to, or are simply thickened areas of, the articular capsule and serve as a direct reinforcement to the capsule. Examples of the latter are the

glenohumeral ligament of the shoulder joint and the iliofemoral, pubofemoral, and ischiofemoral ligaments of the hip joint.

**ARTICULAR CAPSULE.** The articular capsule forms a complete envelope for a freely movable joint. This capsule consists of two layers: an **external fibrous layer** composed of white fibrous connective tissue and an **internal synovial layer**, which is specialized in structure and function and usually is described separately as the synovial membrane.

The **fibrous layer** of the articular capsule is attached to the periosteum along the entire circumference of the articular end of each bone entering the joint, and thus completely surrounds the articulation. Its flexibility permits movement, yet its strength protects the joint from dislocation. Along lines of severe tension, the fibrous capsule is reinforced by ligaments, and it is pierced by nerves and blood vessels which supply it and other intracapsular structures.

The **synovial membrane** covers the inner surface of the fibrous capsule, forming a closed sac called the **synovial cavity**. It is composed of loose connective tissue, cellular in some places, fibrous in others, and it has a free surface of small finger-like projections called the synovial villi. The membrane is thought to elaborate a thick viscous, glairy fluid, similar to the white of an egg and, therefore, termed **synovia** or **synovial fluid**. The synovial membrane covers tendons that pass through certain joints, such as the tendon of the popliteus muscle in the knee and the long head of the biceps in the shoulder. The membrane is not closely applied to the inner surface of the fibrous capsule, but is thrown into folds, fringes, or projections that are composed of connective tissue, fat, and blood vessels. These folds surround the margin of the articular cartilage, filling in clefts and crevices and, in some joints, such as the knee, forming large intra-articular fat pads. The synovial cavity of a normal joint contains only enough synovial fluid to moisten and lubricate the synovial surfaces, but in an injured or inflamed joint, the fluid may accumulate in painful amounts. Part of the lining of the synovial cavity is provided by the surface of articular cartilage that is moistened by synovial fluid but not covered by the synovial membrane.

Similar to the synovial cavities of true joints are the synovial tendon sheaths and synovial bursae, which have an inner lining

equivalent to the synovial membrane of a joint and are lubricated by a fluid similar to synovial fluid.

**SYNOVIAL TENDON SHEATHS.** Synovial tendon sheaths facilitate the gliding of tendons that pass through fibrous and bony tunnels, such as those under the flexor retinaculum of the wrist. These sheaths are closed sacs, the outer or **parietal layer** of the synovial membrane lining the tunnel, and the inner or **visceral layer** reflected over the surface of the tendon. Between these concentrically oriented layers is a fine film of synovial fluid.

**SYNOVIAL BURSAE.** Synovial bursae are located in clefts of connective tissue between muscles, tendons, ligaments, and bones. They are closed sacs of synovial membrane similar to those of a true joint, and may in some cases be continuous, through an opening in the wall, with the lining of a joint cavity. They facilitate the gliding of muscles or tendons over bony or ligamentous prominences, and are named according to their location: subcutaneous, submuscular, or subtendinous. Subcutaneous bursae are found beneath the skin overlying the olecranon at the elbow and the patella at the knee. An example of a submuscular bursa is found deep to the gluteus maximus muscle where it overlies the greater trochanter. Among many other sites, subtendinous bursae are found between the tendon of the obturator internus muscle and the ischium, as well as between the tendon of the semimembranosus and the medial condyle of the tibia.

**LIMITATION OF MOVEMENTS AT JOINTS.** Several factors effectively limit the movement capability at a joint. These include: (1) the tension developed by ligaments, (2) the tension developed by muscles, (3) the natural resistance to continued movement offered by the approximation of soft tissue, and (4) the limitation imposed by the contoured ends of the articulating bones in certain joints.

The **tension developed in ligaments** plays an important part in the prevention of excessive movement at many joints. However, because ligaments are fibrous, they can be stretched by persistent stress and may become incompetent, as is seen when the arches of the foot are no longer supported. Ligaments can, however, prevent a sudden unexpected abnormal movement. An example can be seen in the knee joint where its collateral ligaments are relaxed in flexion, and become taut in extension, thereby helping to limit this latter movement.

The **tension developed by muscles** is perhaps the most important factor in maintaining the stability

of a joint as well as in limiting its movement. The conditions at one joint of a limb may limit the movement of another joint in that same limb because of the muscles passing over the joints. An example of this is the limitation imposed on flexion at the hip joint by the tension of the hamstring muscles when the leg is extended at the knee. When the leg is flexed at the knee joint, however, full flexion at the hip joint can be achieved. This is possible because flexion at the knee joint relaxes the hamstrings, thereby allowing the thigh to overcome the limitation of movement at the hip joint imposed by the taut hamstrings. This phenomenon has been called the *passive insufficiency or ligamentous action of muscles*.

The **approximation of soft tissues** can also be a factor limiting movement at a joint. A simple example of this can be seen in the flexion of the forearm at the elbow joint. As the forearm achieves full flexion, its soft tissues help to limit continued flexion because they press upon the soft tissues on the anterior aspect of the arm.

Finally, in a few joints the **natural contour of the bony articular surfaces** abut in such a manner that continued movement is prevented. Although not encountered as frequently as other limiting mechanisms at joints, it does occur occasionally—for example, at the ankle joint.

## Articulations of the Axial Skeleton

### ARTICULATION OF THE MANDIBLE

**TEMPOROMANDIBULAR JOINT.** Each temporomandibular joint is generally considered to be ellipsoid. It is a synovial joint which is divided into upper and lower synovial cavities by a complete fibrous articular disc. The structures entering into its formation on each side are the anterior part of the mandibular fossa and the articular tubercle of the temporal bone above, and the condyle of the mandible below (Figs. 5-7; 5-8; 5-9).

**Ligaments.** The ligaments of the joint are the following:

- Articular capsule
- Lateral
- Sphenomandibular
- Articular disc
- Stylomandibular

The **articular capsule** is a thin fibrous envelope, attached above to the circumference of the mandibular fossa and the articular tubercle, and below to the neck of the con-

dyle of the mandible. The fibrous disc attaches to the inner surface of the articular capsule. Above the attachment, the capsule is loose in order to allow the disc to slide easily along the temporal bone, whereas below the disc the capsule is more tautly stretched.

The **lateral ligament** (formerly called temporomandibular ligament) strengthens the anterolateral aspect of the fibrous capsule (Fig. 5-7). It is a short, narrow fibrous band attached superiorly to the lower lateral border of the zygomatic process of the temporal bone. Its fibers pass obliquely downward and backward to the lateral surface and posterior border of the neck of the mandible. It is covered by the parotid gland and by the integument.

The **sphenomandibular ligament** (Fig. 5-8) is a flat, thin band of fibrous tissue attached to the spine of the sphenoid bone, and becoming broader as it descends, it is fixed inferiorly to the lingula of the mandibular foramen. It lies somewhat medial to the capsule of the joint, and its upper lateral surface is in relation to the lateral pterygoid muscle and the auriculotemporal nerve. More inferiorly it is separated from the neck of the condyle by the maxillary vessels. Still lower, near its attachment to the mandible, the inferior alveolar vessels and nerve and a lobule of the parotid gland lie between it and the ramus of the mandible. Its medial surface is related inferiorly to the medial pterygoid muscle, while superiorly it lies lateral to the levator veli palatini muscle and the pharyngeal wall. This ligament develops from the sheath of Meckel's cartilage (of the mandibular arch), and some of its ligamentous fibers even penetrate the petrotympanic fissure to attach to the malleus.

The **articular disc** (Fig. 5-9), formed of fibrous tissue, is a thin, oval plate, placed between the condyle of the mandible and the mandibular fossa. Its superior surface is concavoconvex from front to back, to accommodate itself to the form of the mandibular fossa and the articular tubercle. Its inferior surface, in contact with the condyle, is concave. Its circumference is connected to the articular capsule, and anteriorly it attaches to the tendon of the lateral pterygoid muscle. Both medially and laterally the disc is secured to the condyle by fibrous bands. It is thicker at its periphery than at its center. The fibers composing the disc are arranged concentrically, and they are more

FIG. 5-7. The left temporomandibular joint. Lateral view.

apparent at the circumference than at the center. The disc completely divides the joint into two cavities, each of which is lined by a synovial membrane. The two synovial membranes are placed one above, and the other below, the articular disc. The upper one, the larger and looser of the two, is continued from the margin of the cartilage covering the mandibular fossa and articular tubercle onto the superior surface of the disc. The separate cavity below the disc passes from the under-surface of the disc to the neck of the condyle, being prolonged a little farther inferiorly behind than in front. The articular disc is sometimes perforated in its center, and the two cavities then communicate with each other.

The **stylomandibular ligament** (Fig. 5-8) is a specialized band of the cervical fascia and extends from near the apex of the styloid process of the temporal bone to the

FIG. 5-8. The left temporomandibular joint. Medial aspect.

**FIG. 5-9.** A sagittal section through the temporomandibular joint.

angle and posterior border of the ramus of the mandible, between the masseter and medial pterygoid muscles. This ligament separates the parotid from the submandibular gland, and from its deep surface some fibers of the styloglossus muscle take origin. Although classed among the ligaments of the temporomandibular joint, it can only be considered as accessory to it.

**Nerves and Arteries.** The **nerves** of the temporomandibular joint are derived from the auriculotemporal and masseteric branches of the mandibular nerve, and the **arteries** come from the superficial temporal and maxillary branches of the external carotid artery.

**Movements.** Two points should be made initially. It is the mandible that moves, because the maxilla is firmly articulated by sutures to the other bones of the skull, and when the mandible is at rest, the maxillary and mandibular teeth are slightly separated. On contact, the teeth assume their **occlusal position**. The mandible may be **depressed** (jaw

opening) or **elevated** (jaw closing), as well as **protruded** or **retracted**. **Lateral displacement** and some **rotation** of the lower jaw also occur.

It should be borne in mind that there are two parts to this articulation—one between the condyle and the articular disc, and the other between the disc and the mandibular fossa. When the jaw is depressed or elevated, by which the mouth is opened or closed, motion takes place in both parts. The disc glides anteriorly on the articular tubercle, and the condyle moves on the disc like a hinge, causing the mandible to rotate around a horizontal axis whose center of suspension traverses the rami of the mandible near their middle. Near this axis at the lingula, which is adjacent to the mandibular foramen, is attached the sphenomandibular ligament and the sling formed by the masseter and medial pterygoid muscles. When the jaw is opened, the angle of the mandible moves posteriorly while the condyle glides forward as the short arm of a lever, and the chin, as the long arm of the lever, describes a wide arc. The motion between the condyle and the articular disc is largely one of accommodation to the change in position. When the jaw is closed, some of the force is

applied to the condyle as a fulcrum, especially when biting with the incisors; but when chewing with the molars, the pressure comes more directly between the teeth, and the condyle acts more as a guide than as a fulcrum. In protrusion of the mandible, both discs glide forward in the mandibular fossa. During lateral displacement of the mandible, one disc glides forward while the other remains in place. During grinding or chewing movements, there is first a lateral displacement of the mandible by a forward movement of one condyle, and then the mandible is brought back into place by the action of the closing muscles and the meshing of the teeth. The condyles may be displaced alternately, or the same one may be displaced repeatedly as when chewing with the teeth of one side.

The *mandible is depressed*, and the mouth thereby opened, by the lateral pterygoid muscles, which are assisted by the digastric, mylohyoid, and geniohyoid muscles. Conversely, the *mandible is elevated*, and the mouth closed, by the masseter, medial pterygoid, and temporalis muscles. The *mandible is protruded* by the simultaneous action of the lateral pterygoids of both sides and the synergetic action of the closing muscles. It is *retracted* by the posterior fibers of the temporalis, and *displaced laterally* by the action of the opposite lateral pterygoid muscle.

## ARTICULATION OF THE VERTEBRAL COLUMN WITH THE CRANIUM

**ATLANTO-OCIPITAL JOINTS** (Figs. 5-10; 5-11). The atlanto-occipital joints, one on each side, interconnect the concave superior articular facets of the lateral masses of the atlas and the convex condyle of the occipital bone. These two synovial joints are ellipsoid and the articular surfaces are reciprocally curved.

**Ligaments.** The ligaments connecting the bones are:

- Two articular capsules
- Anterior atlanto-occipital membrane
- Posterior atlanto-occipital membrane

The **articular capsules** invest each of the two joints and surround the condyles of the occipital bone, connecting them with the superior articular facets of the atlas. Although they are loosely fit, they are quite distinct. On their medial side, however, they are thin and formed only of loose fibers, whereas laterally they are reinforced by

**Fig. 5-10.** The atlanto-occipital and lateral atlantoaxial joints. Anterior aspect. On the left side the articular capsule and part of the atlanto-occipital membrane covering the atlantoaxial joint have been removed, as has the capsule surrounding the lateral atlantoaxial joint.

FIG. 5-11. The atlanto-occipital and atlantoaxial joints. Posterior aspect.

oblique bands (sometimes called the lateral atlanto-occipital ligaments), which are directed upward and medialward.

The **anterior atlanto-occipital membrane** (Fig. 5-10) is about 2 cm wide and is composed of densely woven fibers, which pass between the anterior margin of the foramen magnum above, and the cranial border of the anterior arch of the atlas below. Laterally it is continuous with the articular capsules, and anteriorly it is strengthened in the midline by a strong, round cord that is continuous with the anterior longitudinal ligament and connects the basilar part of the occipital bone to the tubercle on the anterior arch of the atlas. Deep to the membrane is the ventral aspect of the dura mater covering the upper cervical spinal cord at its medullary junction, while anterior to it are found the alar ligaments and the lateral and anterior rectus capitis muscles.

The **posterior atlanto-occipital membrane** (Fig. 5-11) is a little broader than but not so dense as the anterior membrane. It is a thin fibrous layer, connected above to the posterior margin of the foramen magnum and below to the superior border of the posterior arch of the atlas. On either side this membrane is defective over the groove for the vertebral artery (Fig. 5-11), and forms, with this groove, an opening for the passage of the artery into the central nervous system and for the first cervical spinal nerve (suboccipital nerve) to exit from the underlying

spinal cord. The free border of the membrane, arching over the artery and nerve, is sometimes ossified. Dorsal to the membrane are found the rectus capitis posterior minor and obliquus capitis superior muscles, while ventrally the membrane is intimately adherent to the dura mater of the vertebral canal.

**Synovial Membranes.** There are two synovial membranes: one lining each of the articular capsules. The atlanto-occipital joints frequently communicate medially with the joint between the dorsal surface of the dens and the transverse ligament of the atlas.

**Nerves and Arteries.** The nerve supply to the atlanto-occipital joints comes from sensory fibers of the first cervical (suboccipital) nerve. Its **arterial supply** comes from branches of the vertebral artery and from meningeal branches of the ascending pharyngeal artery.

**Movements.** The movements permitted in this joint are (1) flexion and extension, which give rise to the ordinary forward and backward nodding of the head, and (2) slight lateral tilting of the head to one or the other side. **Flexion** is produced mainly by the action of the longus capitis and rectus capitis anterior muscles. **Extension** results from the action of the rectus capitis posterior major and minor muscles, as well as the obliquus capitis superior, semispinalis capitis, splenius capitis, sternocleidomastoideus, and upper fibers of the trapezius. **Lateral flexion** (lateral tilting movement) is produced by the rectus capitis lateralis muscle assisted by the trapezius, splenius capitis, semispinalis capitis, and sternocleidomastoid muscles of the same side, all acting together.

**Ligaments Connecting the Axis with the Occipital Bone.** Although the occipital bone and the axis are not directly in contact, they are united by ligaments that are observable at dissection after the removal of the posterior arches of the atlas and axis. These occipitoaxial ligaments include:

- Tectorial membrane
- Two alar
- Apical

The **tectorial membrane** (Figs. 5-12; 5-14) is a broad, strong band which covers the dens and its ligaments posteriorly. It courses within the vertebral canal and appears to be a cranial prolongation of the posterior longitudinal ligament of the vertebral column. It is fixed below to the dorsal surface of the body of the axis and, expanding as it ascends, is attached to the basilar portion of the occipital bone ventral to the foramen magnum, where it blends with the cranial dura mater. Its ventral surface is in relation with the transverse ligament of the atlas, and its dorsal surface with the dura mater.

The **alar ligaments** (Figs. 5-12; 5-13) are strong, round cords, which arise one on each side of the cranial part of the dens and, passing obliquely upward and lateralward, are inserted into the rough depressions on the medial sides of the condyles of the occipital bone. The alar ligaments limit rotation of the cranium and therefore are sometimes referred to as **check ligaments**.

The **apical ligament of the dens** (Figs. 5-13; 5-14) is a fibrous cord in the triangular interval between the two alar ligaments. It extends from the tip of the dens to the anterior margin of the foramen magnum, being intimately blended with the deep portion of the anterior atlanto-occipital membrane and superior crus of the transverse ligament of the atlas. It is regarded as a rudimentary intervertebral disc, and in it traces of the notochord may persist.

In addition to the ligaments that unite the atlas and axis to the skull, the **ligamentum nuchae** must be regarded as one of the ligaments connecting the vertebral column with the cranium.

**Fig. 5-12.** Exposure of the cruciform ligament after removal of the posterior arches of the atlas and axis and after cutting and reflecting the tectorial membrane. Observe that the cruciform ligament consists of a longitudinal band and a transverse ligament which lie posterior to the dens and its alar and apical (hidden) ligaments.

**FIG. 5-13.** The alar ligaments and the apical ligament of the dens are exposed after the removal of the cruciform ligament. Note that this is a posterior approach to the dens after cutting through the posterior arches of the atlas and axis.

**FIG. 5-14.** Median sagittal section through the occipital bone and first three cervical vertebrae. (From Spalteholz.)

## ARTICULATIONS OF THE ATLAS WITH THE AXIS

The atlas and the axis articulate by means of three joints. On each side the inferior articular facet of the lateral mass of the atlas articulates with the superior articular facet of the axis to form the **lateral atlantoaxial joints**. In addition, the dens of the axis articulates with the anterior arch and transverse ligament of the atlas to form the **median atlantoaxial joint**.

**LATERAL ATLANTOAXIAL JOINT** (Figs. 5-12; 5-13). These two articulations, one on each side, are classified as plane joints. Surrounded by an articular capsule, each flat or slightly convex inferior articular facet of the atlas fits on the smooth upwardly directed superior articular facets of axis in order to allow rotation of the atlas on the axis.

**Ligaments.** Although the only officially recognized ligaments of these joints per se are their capsules, the atlantoaxial extensions of two other ligaments of the spinal column may be considered as helping to secure these two bones, thereby lending additional integrity to the joints. The ligaments to be described therefore are:

- Two articular capsules
- Anterior atlantoaxial
- Posterior atlantoaxial

The **articular capsules** (Figs. 5-12; 5-13) are thin and loose, and connect the margins of the lateral masses of the atlas with those of the posterior articular surfaces of the axis. Each is strengthened at its posterior and medial part by an **accessory ligament**, which is attached below to the body of the axis near the base of the dens, and above to the

lateral mass of the atlas near the transverse ligament. The inner aspect of the capsules is lined by a synovial membrane.

The **anterior atlantoaxial ligament** (Figs. 5-10; 5-14) is a strong membrane fixed to the inferior border of the anterior arch of the atlas, and to the ventral surface of the body of the axis. It is strengthened in the midline by a round cord, which connects the tubercle on the anterior arch of the atlas to the body of the axis and is a continuation cranially of the anterior longitudinal ligament. Immediately anterior and coursing vertically along each lateral border of the ligament are the longus capitis muscles.

The **posterior atlantoaxial ligament** (Figs. 5-11; 5-14) is a broad, thin membrane attached above to the inferior border of the posterior arch of the atlas, and below to the superior edges of the laminae of the axis. At the atlantoaxial level, this ligament is comparable to the intervertebral ligamenta flava found connecting the posterior arches of other lower vertebrae.

**MEDIAN ATLANTOAXIAL JOINT.** This pivot joint contains two synovial cavities located between the dens of the axis and a ring formed by the anterior arch of the atlas and the transverse ligament of the atlas (Fig. 5-15). One synovial cavity lies between the dens and the anterior arch of the atlas, while the other is interposed between the dens and the transverse ligament of the atlas.

**Ligaments.** The **transverse ligament of the atlas** (Figs. 5-12; 5-14; 5-15) is a thick, strong band which arches across the ring of the atlas and retains the dens in contact with the anterior arch. It is broader and thicker in the middle than at the ends, and is firmly attached on each side to a small tubercle on

**FIG. 5-15.** The median atlantoaxial joint viewed from above the atlas. Note the two synovial cavities, one anterior and the other posterior to the upwardly projecting dens of the axis.

the medial surface of the lateral mass of the atlas. As it crosses the dens, a small fasciculus is prolonged cranially, and another caudally, from the superficial or posterior fibers of the ligament, forming a **longitudinal band**. The superior band is attached to the basilar part of the occipital bone, closely related to the tectorial membrane, while the inferior band is fixed to the posterior surface of the body of the axis. Together with the transverse ligament, these two parts of the longitudinal band form a cross-like structure named the **cruciate ligament of the atlas** (Fig. 5-12). The transverse ligament divides the entire circular opening in the atlas into two unequal parts: the posterior and larger portion contains the spinal cord, its membranes and vessels, and the spinal trunks of the accessory nerves; the anterior and smaller part contains the dens. The neck of the dens is constricted where it is embraced posteriorly by the transverse ligament, so that this ligament suffices to hold it in position after all the other ligaments have been divided.

**Synovial Membranes.** There is a synovial membrane for each of the lateral atlantoaxial joints, and two synovial cavities associated with the median atlantoaxial joint. The joint cavity between the dens and the transverse ligament of the atlas may be continuous laterally with those of the atlanto-occipital articulations.

**Movements.** The atlantoaxial joints allow rotation of the atlas (and with it the skull) upon the axis, the extent of rotation being limited by the alar ligaments.

The opposed articular surfaces of the lateral atlantoaxial joints are not reciprocally curved, because both are convex in their long axes. Thus, when the superior facet glides ventrally on the inferior, it also descends. The fibers of the articular capsule are then relaxed in a vertical direction, thereby permitting movement. As the atlas and the skull pivot around the dens, the lateral masses of the atlas at the lateral atlantoaxial joints glide, one forward and the other backward, upon the superior articular facets of the axis.

The principal muscles by which these movements are produced are the sternocleidomastoid and semispinalis capitis *of one side*, acting with the longus capitis, splenius, longissimus capitis, rectus capitis posterior major, and the obliquus capitis inferior *of the other side*.

## ARTICULATIONS OF THE VERTEBRAL COLUMN

Interconnecting each succeeding vertebra from the axis to the sacrum are: a **series of cartilaginous joints** that unite each adjacent

pair of vertebral bodies by means of longitudinal ligaments and intervertebral discs; and a **series of synovial joints**, reinforced by ligaments that unite the vertebral arches of the vertebrae at their interfacing articular processes.

### JOINTS BETWEEN THE VERTEBRAL BODIES.

The articulations between the bodies of the vertebrae are separated by fibrocartilaginous intervertebral discs and are classified as symphyses. The individual vertebrae move only slightly on each other, but because this slight degree of movement between the pairs of bones takes place in all the joints of the vertebral column, the total range of movement is considerable.

**Ligaments.** The ligaments of these articulations are the following:

Anterior longitudinal  
Posterior longitudinal  
Intervertebral discs

The **anterior longitudinal ligament** (Figs. 5-10; 5-14; 5-16; 5-19) is a broad and strong band of fibers which extends along the anterior surfaces of the bodies of the vertebrae, from the axis to the sacrum. Its extension to the occipital bone may (as it is in this book) be referred to as the anterior atlantoaxial ligament. Being relatively narrower above, the anterior longitudinal ligament broadens somewhat as it descends. It is a bit narrower (but thicker) in its passage over the vertebral bodies than over the intervertebral discs. It consists of dense longitudinal fibers that are intimately adherent to the intervertebral discs and the prominent margins of the vertebrae, but not attached firmly to the middle parts of the bodies. In the latter situation the ligament is thick and serves to fill the concavities on the ventral surfaces, giving the anterior aspect of the vertebral column a more even contour. It is composed of several layers of fibers which vary in length, but are closely interlaced with each other. The most superficial fibers are the longest and extend across four or five vertebrae. A second, subjacent set extends between two or three vertebrae, while a third set, the shortest and deepest, reaches from one vertebra to the next. At the sides of the vertebral bodies, a few short fibers of the ligament pass from one vertebra to the next. These fibers are separated from the concavities of the vertebral bodies by oval apertures for the passage of vessels.

FIG. 5-16. Median sagittal section of two lumbar vertebrae and their ligaments.

The **posterior longitudinal ligament** (Figs. 5-12; 5-14; 5-16; 5-17) extends along the dorsal surfaces of the bodies of the vertebrae from the axis to the sacrum. It lies within the vertebral canal (Fig. 5-16), and it is continued above the axis as the tectorial membrane. It is broader above than below, and thicker in the thoracic region than in the cervical and lumbar regions. The ligament broadens somewhat and becomes more intimately adherent as it passes over each of the intervertebral discs and contiguous margins of the vertebrae. The ligament is smooth superiorly, but in the thoracic and lumbar regions it presents a series of dentations with intervening concave margins. It is narrow and thick over the centers of the bodies, from which it is separated by the basivertebral veins. The ligament is composed of longitudinal fibers, which are denser and more compact than those of the anterior ligament. Its superficial layers occupy the interval between three or four vertebrae, while the deeper layers extend between adjacent vertebrae.

The **intervertebral discs** (Figs. 5-16; 5-20) are interposed between the adjacent surfaces of the vertebral bodies from the axis to the sacrum, forming their chief bonds of connection. They vary in shape and thickness in different parts of the vertebral col-

FIG. 5-17. Posterior longitudinal ligament of the vertebrae in the lumbar region. Interior of spinal column with the dorsal arches cut and viewed from the posterior aspect.

umn. Their shape corresponds to the surfaces of the bodies between which they are placed, except in the cervical region, where they are slightly smaller from side to side than the corresponding bodies. Their thickness varies not only in the different regions of the column, but in different parts of the same disc. In the cervical and lumbar regions the discs are thicker ventrally than dorsally, and thus contribute to the anterior convexities of these parts of the column. The discs are of nearly uniform thickness in the thoracic region, and the anterior concavity of this part of the column is due almost entirely to the shape of the vertebral bodies. From the axis to the sacrum, the intervertebral discs constitute about one-fourth of the length of the vertebral column. Being thicker in the cervical and lumbar regions, the discs account for a greater proportion of the length of the spinal column in these regions than in the thoracic region. Correspondingly, the cervical and lumbar regions show a greater pliancy and freedom of movement. The intervertebral discs are adherent to thin layers of hyaline cartilage which cover the superior and inferior surfaces of the bodies of the vertebrae. Between the lower cervical vertebrae, however, small joints lined by synovial membranes are occasionally present between the superior surfaces of the bodies and the margins of the discs on either side. The rounded border of the intervertebral discs are firmly attached to the anterior and posterior longitudinal ligaments. In the thoracic region the discs are joined laterally, by means of interarticular ligaments, to the heads of those ribs that articulate with the two adjacent vertebrae.

**Structure of the Intervertebral Discs.** Each disc is composed of outer laminae of fibrous tissue and fibrocartilage called the **anulus fibrosus**, and an inner core of soft, gelatinous and highly elastic substance called the **nucleus pulposus**.

The laminae forming the **anulus fibrosus** are arranged in concentric rings and the outermost consist of ordinary fibrous tissue; those closer to the center are formed of white fibrocartilage. The laminae are not quite vertical in their direction, those near the circumference being curved outward and closely approximated, while those nearest the center curve in the opposite direction, and are somewhat more widely separated. The fibers composing the laminae pass obliquely between the two adjacent vertebrae and are firmly attached to them. Greater stability is achieved in the disc because the fibers of each adja-

cent lamina pass in opposite directions, crossing one another like the limbs of the letter X. This laminar arrangement characterizes the outer half of each fibrocartilage.

The yellowish **nucleus pulposus** is more abundant in the cervical and lumbar regions than at thoracic levels, and it projects considerably above the surrounding anulus fibrosis if the disc is divided horizontally. Situated somewhat behind the center of the disc, the nucleus pulposus consists of a fine fibrous matrix within which are found some polymorphic cells. Although at birth the nucleus pulposus can be considered as a remnant of the notochord, it undergoes such structural changes with maturation that by adolescence its notochordal cells have been almost entirely replaced by cartilaginous cells from the surrounding anulus fibrosus. With age, the gelatinous substance is replaced by fibrocartilage, and there is more of a blending of the anulus fibrosus with the central core. There is also a decrease in the water content of the nucleus pulposus along with a reduction in its elasticity.

**Clinical Correlation.** Intervertebral discs cushion mechanical shocks imposed on the vertebral column, thereby distributing the pressure more evenly. Upon receiving a jolting impact, the highly elastic nucleus pulposus becomes flatter and broader and pushes the more resistant fibrous laminae outward in all directions. The nucleus and anulus then return to their original position after the impact is dissipated. Discs are secured between the vertebrae primarily by the anterior and posterior longitudinal ligaments. In older individuals an unusual strain may result in the disc proper, or the nucleus pulposus only, being extruded beyond its intervertebral position and then not returning to its proper site. Such a situation generally produces pain because the protruded disc presses upon spinal roots or nerves. Most commonly this condition is seen in the lower lumbar region with accompanying radiating pain to the gluteal region and lower extremity.

#### JOINTS BETWEEN THE VERTEBRAL ARCHES.

Joints between articular processes of the vertebrae are plane or gliding joints, enveloped by capsules lined by synovial membrane.

**Ligaments.** **Articular capsules** (Fig. 5-16) are thin, loose, and attached to margins of the articular processes of adjacent vertebrae. They are longer and looser in the cervical than in the thoracic and lumbar regions.

The laminae, spinous, and transverse processes of the vertebrae are connected by the following ligaments:

- Ligamenta flava
- Supraspinal
- Ligamentum nuchae
- Interspinal
- Intertransverse

The **ligamenta flava** (Figs. 5-16; 5-18; 5-23) connect the laminae of adjacent vertebrae from the axis to the first segment of the sacrum. Although best seen from the interior of the vertebral canal, when viewed from the outer surface they appear short because they are overlapped by the laminae. Each ligament consists of two lateral portions, which commence on each side at the roots of the articular processes surrounded by the capsule and extend dorsally to the point where the laminae meet to form the spinous process. The dorsal margins of the two portions are in contact except for slight intervals at the midline through which pass vertebral veins. Each *ligamentum flavum* consists of yellow elastic tissue, the fibers of which, almost perpendicular in direction, are attached to the ventral surface of the lamina above and to the dorsal surface and superior margin of the lamina below. In the cer-

vical region the ligaments are thin, but broad and long. They are thicker in the thoracic region and thickest in the lumbar region. Their marked elasticity permits separation of the laminae during flexion of the vertebral column, and also serves to preserve the upright posture.

The **supraspinal ligament** (Figs. 5-16; 5-23) is a strong fibrous cord which connects together the apices of the spinous processes from the seventh cervical vertebra to the sacrum. At its points of attachment to the tips of the spinous processes, fibrocartilage is developed in the ligament. It is thicker and broader in the lumbar than in the thoracic region, and intimately blended in both situations with the neighboring fascia. The most superficial fibers of this ligament extend over three or four vertebrae; those coursing more deeply pass between two or three vertebrae, while the deepest connect the spinous processes of neighboring vertebrae and become continuous with the interspinal ligaments. Above the seventh cervical vertebra it is continued to the external occipital protuberance and median nuchal line as the **ligamentum nuchae**.

The **ligamentum nuchae** is a fibroelastic membrane in the dorsal neck which corresponds to the supraspinal ligament of the lower vertebrae. It extends from the external occipital protuberance and median nuchal line to the spinous process of the seventh cervical vertebra. In its course a fibrous lamina from the ligamentum nuchae attaches initially to the posterior tubercle of the atlas and the spinous processes of the cervical vertebrae, and then forms a septum between the muscles on both sides of the neck. In man, it is merely the rudiment of an important elastic ligament seen in some of the grazing animals which serves to sustain the weight of the head and to assist in flexion of the cervical vertebrae.

The **interspinal ligaments** (Fig. 5-16) are thin and membranous and interconnect adjoining spinous processes. Their attachment extends from the root to the apex of each spinous process and, thereby, they meet the *ligamenta flava* ventrally and the supraspinal ligament dorsally. They are narrow and elongated in the thoracic region, but broad, thick, and quadrilateral in shape in the lumbar region. These ligaments are only slightly developed in the neck.

**FIG. 5-18.** The ligamenta flava of the lumbar region. The interior of the spinal column is seen with the vertebral bodies cut away. This demonstrates the dorsal laminae viewed from the anterior aspect.

The **intertransverse ligaments** (Figs. 5-19; 5-23) are interposed between the transverse processes. In the cervical region they consist of a few irregular, scattered fibers; in the thoracic region they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

**MOVEMENTS OF THE VERTEBRAE.** The movements permitted in the vertebral column are: **flexion, extension, lateral flexion, circumduction, and rotation.**

In **flexion**, or bending ventrally, the anterior longitudinal ligament is relaxed, and the anterior portions of the intervertebral fibrocartilages are compressed. The posterior longitudinal ligament, the ligamenta flava, and the interspinal and supraspinal ligaments

are stretched, as also are the dorsal fibers of the intervertebral discs. The interspaces between the laminae are widened, and the inferior articular processes glide upward upon the superior articular processes of the subjacent vertebrae. Tension of the extensor muscles of the back is the most important factor in limiting the movement. Flexion is the most extensive of all the movements of the vertebral column, and it is freest in the cervical region.

In **extension**, or bending dorsally, an opposite disposition of the parts takes place. Thus, the distance between the anterior borders of the vertebrae is increased while their posterior borders are moved closer together. This movement is limited by the anterior longitudinal ligament and by an approximation of the spinous processes. It is freest in the cervical and lumbar regions.

In **lateral flexion**, the sides of the intervertebral discs are compressed, the extent of motion being

**FIG. 5-19.** The costovertebral joints viewed from the right lateral aspect. Note the two synovial cavities exposed in the lowest joint from which have been removed much of the radiate ligament and the head of the rib. Observe that each rib articulates with two adjacent vertebral bodies.

limited by the resistance offered by opposing muscles and by the surrounding ligaments. This movement may take place in any part of the column, but is freest in the cervical and lumbar regions, and is always associated with a certain degree of rotation.

**Circumduction** is limited, and is merely a succession of the preceding movements.

**Rotation** is produced by the turning of adjacent vertebrae at the joints between the vertebral arches, which then produces a twisting of the intervertebral discs. Although only slight rotation can occur between any two vertebrae, a considerable extent of movement is allowed when it takes place at the same time in the whole length of the column. This movement occurs most freely in the thoracic region, but also occurs to a slight extent at cervical and lumbar levels of the spinal column.

The extent and variety of the movements are influenced by the shape and direction of the articular surfaces. In the **cervical region** the upward inclination of the superior articular surfaces allows free flexion and extension. *Extension* can be carried farther than flexion. At the cranial end of the cervical region, it is checked by the locking of the posterior edges of the superior atlantal facets in the condyloid fossae of the occipital bone. At the caudal end of the cervical region, extension is limited by a mechanism whereby the inferior articular processes of the seventh cervical vertebra slip into grooves behind and below the superior articular processes of the first thoracic. *Flexion* is arrested just beyond the point where the cervical convexity is straightened. The movement is checked by the apposition of the projecting lower lips of the bodies of the vertebrae with the shelving surfaces on the bodies of the subjacent vertebrae. *Lateral flexion* and *rotation* are relatively free in the cervical region, but the two movements are always combined. The inclinations of the superior articular surfaces impart a rotatory movement during lateral flexion, while pure rotation is prevented by the slight medial slope of these surfaces.

In the **thoracic region**, notably in its upper part, all the movements are limited in order to minimize interference with respiration. The almost complete absence of an upward inclination of the superior articular surfaces prohibits any marked *flexion*, whereas *extension* is checked by the contact of the inferior articular margins with the laminae, and the contact of the spinous processes with one another. The mechanism at the caudal end of the cervical region that limits extension also serves to limit flexion of the thoracic region when the neck is extended. *Rotation* is free in the thoracic region. The position of the articular processes allows rotation around a vertical axis that passes through the bodies of the midthoracic vertebrae, but anterior to the vertebral bodies of the upper and lower thoracic vertebrae. The direction of the articular facets would allow free lateral flexion, but this movement is considerably limited by the resistance of the ribs and sternum.

In the **lumbar region** *extension* is free and wider

in range than *flexion*. The inferior articular facets are not in close apposition with the superior facets of the subjacent vertebrae, and because of this a considerable degree of lateral flexion is permitted. For the same reason a slight amount of rotation can be achieved, but this is checked so soon by the interlocking of the articular surfaces that it is negligible.

**MUSCLE ACTIONS ON THE VERTEBRAE.** The principal muscles that produce **flexion** are the sternocleidomastoid, the longus capitis, the longus colli, the scalenes, the abdominal muscles, and the psoas major. **Extension** is produced by the intrinsic muscles of the back (erector spinae), assisted in the neck by the splenius, the semispinales, and the multifidi. **Lateral flexion** is produced by the intrinsic muscles of the back, by the splenius, the scalenes, the quadratus lumborum, and the psoas major when the muscles of one side only are acting. **Rotation** results from the action of the following muscles of one side only, the sternocleidomastoid, the longus capitis, the scalenes, the multifidi, the rotatores, the semispinalis capitis, and the abdominal muscles.

## COSTOVERTEBRAL JOINTS

The articulations of the ribs with the vertebral column may be divided into two sets, one connecting the heads of the ribs with the bodies of the vertebrae, and the other uniting the necks and tubercles of the ribs with the transverse processes.

**ARTICULATIONS OF THE HEADS OF THE RIBS** (Fig. 5-19). These constitute a series of plane or gliding joints, and are formed by the articulation of the heads of the typical ribs with the facets on the contiguous margins of the bodies of the thoracic vertebrae, and with the intervertebral discs between them. Whereas the first, tenth, eleventh, and twelfth ribs each articulate with a single vertebra, the heads of the second to the ninth ribs each articulate by means of two facets, a superior and an inferior, with two adjacent vertebral bodies. The articulation of the head of each rib, however, is considered a single joint because there is but one articular capsule, even though there may be two synovial sacs.

**Ligaments.** The ligaments at each joint are:

- Articular capsule
- Radiate
- Intra-articular

The **articular capsule** surrounds the joint and is composed of short, strong fibers that connect the head of the rib with the circum-

ference of the articular cavity formed by the intervertebral disc and the adjacent vertebrae. The capsule is most distinct at the superior and inferior parts of the articulation. Some of its upper fibers pass through the intervertebral foramen to the back of the intervertebral disc, while the posterior fibers of the capsule are continuous with the costovertebral ligament.

The **radiate ligament** (Fig. 5-19) connects the anterior part of the head of each rib with the side of the bodies of two vertebrae, and the intervertebral disc between them. It consists of several flat fasciculi which are attached to the anterior part of the head of the rib, just beyond the articular surface. The more superior fasciculi are connected with the body of the vertebra above, while the inferior fibers attach to the body of the vertebra below. The middle fibers are short and less distinct and course horizontally to attach to the intervertebral disc. The radiate ligaments along the spinal column are in relationship anteriorly to the thoracic ganglia of the sympathetic trunk, the pleura, and—on the right side—the azygos vein. Immediately behind the radiate ligaments at each level are the intra-articular ligament and the synovial membranes (Fig. 5-19).

In the case of the first rib, the fibers of the radiate ligament are attached to the body of the last cervical vertebra, as well as to that of the first thoracic. In the articulations of the heads of the tenth, eleventh, and twelfth ribs, each of which articulates with a single vertebra, the fibers of the radiate ligament in each case connect to the vertebra above, as well as to that with which the rib articulates.

The **intra-articular ligament** (Fig. 5-19) is situated in the interior of the joint. It consists of a short, flat band of fibers, attached by one extremity to the crest separating the two articular facets on the head of the rib, and by the other to the intervertebral disc. It divides the joint into two cavities, each of which is lined by a synovial membrane. In the joints of the first, tenth, eleventh, and twelfth ribs, the intra-articular ligament does not exist because there is but one cavity and one synovial membrane at each of these articulations.

**COSTOTRANSVERSE JOINTS** (Fig. 5-20). The articular surface on the tubercle of the upper ten ribs forms a plane or gliding joint with the articular facet on the adjacent transverse process of the corresponding vertebra. In the eleventh and twelfth ribs this articulation is wanting.

**FIG. 5-20.** The costovertebral joints viewed from the superior aspect. Note that on the right side the synovial cavities of the joint of the head of the rib and the costotransverse joint have been exposed.

**Ligaments.** The ligaments of the joint are:

- Articular capsule
- Superior costotransverse
- Costotransverse
- Lateral costotransverse

The **articular capsule** is a thin, fibrous membrane attached to the circumference of the articular surfaces. As in other plane joints, the capsule is lined by a synovial membrane.

The **superior costotransverse ligament** (Figs. 5-19; 5-20; 5-23) is attached to the sharp crest on the superior border of the neck of the rib, and passes obliquely upward and laterally to the lower border of the transverse process immediately above. The anterior layer of this ligament blends laterally with the internal intercostal membrane and is crossed by the intercostal vessels and nerves. Its posterior layer blends laterally with the external intercostal muscle. Its medial border is thickened and free, and bounds an aperture that transmits the posterior branches of the intercostal vessels and nerves.

The first rib has no superior costotransverse ligament. The neck of the twelfth rib is connected to the base of the transverse process of the first lumbar vertebra by a band of fibers, the **lumbocostal ligament**, which actually lies in series with the superior costotransverse ligaments. It is merely a thickened portion of the lumbocostal aponeurosis or anterior layer of the thoracolumbar fascia.

The **costotransverse ligament** (Figs. 5-20; 5-23) is sometimes called the ligament of the neck of the rib and consists of short but strong fibers connecting the rough surface on the back of the neck of the rib with the anterior surface of the adjacent transverse process. It is observed best with a vertebra cut in transverse section, where it can be seen to fill the **costotransverse foramen**. A rudimentary ligament only may be present in the case of the eleventh and twelfth ribs.

The **lateral costotransverse ligament** (Figs. 5-20; 5-23) is a short, thick, and strong fasciculus, which passes obliquely from the apex of the transverse process of the vertebra to the rough and nonarticular portion of the tubercle of the corresponding rib. For this

**Fig. 5-21.** Anteroposterior view of lower cervical and upper thoracic vertebrae of adult. The skull obscures the upper cervicals. (Courtesy of Doctors Moreland and Arndt.)

reason it has also been called the ligament of the tubercle of the rib. The ligaments attached to the upper ribs ascend from the transverse processes, and are shorter and more oblique than those attached to lower ribs, which descend slightly.

#### **Movements at the Costotransverse Joints.**

The heads of the ribs are so closely connected to the bodies of the vertebrae by the radiate and intra-articular ligaments that only slight gliding movements of the articular surfaces on one another can take place. Similarly, the strong ligaments binding the necks and tubercles of the ribs to the transverse processes limit the movements of the costotransverse joints to slight gliding, the nature of which is determined by the shape and direction of the articular surfaces. In the upper six ribs the articular surfaces on the tubercles are *oval in shape and convex from above downward*. They fit into corresponding concavities on the *anterior surfaces* of the transverse process, so that upward and downward movements of the tubercles are associated with rotation of the rib neck on its long axis. On the seventh to the tenth ribs the articular surfaces on the tubercles are *flat, and directed obliquely downward, medialward, and backward*. The surfaces with which they articulate are placed

on the *upper margins* of the transverse processes, and therefore, when the tubercles are drawn up, they are at the same time carried backward and medialward. The joints of the heads of the ribs and the costotransverse joints move simultaneously and in the same directions, the total effect being that the neck of the rib moves as if on a single joint, of which the two articulations form the ends. The necks of the upper six ribs only move slightly upward and downward. Their chief movement is one of rotation around their own long axes. Thus, rotation backward of the neck of the rib results in depression of the anterior end of the rib, whereas rotation forward of the neck causes elevation of the anterior end. The necks of the seventh to tenth ribs may move either upward, backward, and medialward, or downward, forward, and lateralward, thereby altering the shape of the rib cage. Only slight rotation accompanies these movements.

#### **STERNOCOSTAL, INTERCHONDRAL, AND COSTOCHONDRAL JOINTS**

**STERNOCOSTAL JOINTS** (Fig. 5-24). At the anterior aspect of the thoracic wall, the bony portion of each rib becomes continuous with

**Fig. 5-23.** A part of the thoracic spinal column shown from the posterior aspect. Observe the necks of the ribs and the costotransverse joints with their associated ligaments. (From Benninghoff and Goertler, 1975.)

the lateral end of a strip of cartilage, the **costal cartilage**, resulting in a series of costochondral unions. The medial ends of the costal cartilages fit into slight concavities along the lateral borders of the sternum, forming the **sternocostal joints**. With the exception of the first rib, the sternocostal articulations are plane or gliding joints with synovial cavities. The costal cartilage of the first rib is directly united with the sternum and forms a typical synchondrosis.

**Ligaments.** The ligaments at the sternocostal joints are:

- Articular capsules
- Radiate sternocostal
- Intra-articular sternocostal
- Costoxiphoid

**Articular capsules** surround the joints between the sternum and the cartilages of the second to seventh ribs. They are thin, intimately blended with the radiate sternocostal ligaments, and strengthened at the upper and lower parts of the articulations by a few fibers that connect the cartilages to the side of the sternum.

The **radiate sternocostal ligaments** (Fig. 5-24) consist of broad and thin membranous bands that radiate from the ventral and dorsal surfaces of the sternal ends of the cartilages of the true ribs to the anterior and posterior surfaces of the sternum. They are composed of fibers that course obliquely superiorly, transversely and obliquely inferiorly, intermingling with fibers of the ligaments above and below them, with those of the opposite side, and ventrally with the ten-

dinous fibers of origin of the pectoralis major muscle. Together these structures form a thick fibrous membrane that envelops the sternum. This is more distinct over the inferior than over the superior part of the bone.

The **intra-articular sternocostal ligaments** are found constantly only between the second costal cartilages and the sternum. The cartilage of the second rib is connected with the sternum by means of an intra-articular ligament, attached at its lateral end to the cartilage of the rib, and medially to the fibrocartilage that unites the manubrium and body of the sternum. The second sternocostal joint contains two synovial membranes. Between these is the intra-articular ligament, which then continues medially within the manubriosternal joint. Occasionally the cartilage of the third rib is connected with the first and second sternbrae of the body of the sternum by a similar ligament. Intra-articular ligaments may rarely be seen in the lower sternocostal joints in association with the original sternbrae that formed the sternal body. At times the intra-articular ligament obliterates the synovial cavity completely, thereby transforming the joint into a synchondrosis.

The **costoxiphoid ligaments** connect the anterior and posterior surfaces of the seventh costal cartilage, and sometimes those of the sixth, to the dorsal and ventral surfaces of the xiphoid process. They vary in length and breadth in different subjects, the dorsal ligaments being less distinct than the ventral.

FIG. 5-24. Sternocostal and interchondral articulations. Anterior view.

**Synovial Membranes.** There is no synovial membrane between the first costal cartilage and the sternum because this cartilage is directly continuous with the manubrium. There are generally two in the articulation of the second costal cartilage and usually one in each of the other joints. The synovial cavities of the sixth and seventh sternocostal joints are sometimes absent, and when an intra-articular ligament is present, there are two synovial cavities. After middle life the articular surfaces of the cartilages of most of the ribs become continuous with the sternum, and the joint cavities are consequently obliterated.

**Movements.** Slight gliding movements are permitted in the sternocostal articulations.

**Arteries and Nerves.** The arterial supply to the sternocostal joints is derived from perforating branches of the internal thoracic arteries. The nerves come from the anterior perforating branches of the intercostal nerves.

**INTERCHONDRAL ARTICULATIONS** (Fig. 5-24). The contiguous borders between the sixth and seventh, the seventh and eighth, the eighth and ninth, and sometimes those of the ninth and tenth costal cartilages articulate with each other by small, smooth, oblong facets. Each joint is enclosed in a thin articular capsule, lined by synovial membrane

and strengthened laterally and medially by fibrous **interchondral ligaments** which pass from one cartilage to the other. Sometimes the fifth costal cartilages, more rarely the ninth and tenth, articulate by their lower borders with the adjoining cartilages by small oval facets. More frequently, however, this connection consists simply of a few ligamentous fibers.

**COSTOCHONDRAL ARTICULATIONS.** The lateral end of each costal cartilage is received into a slight depression in the sternal end of the rib. The cartilage and bone are bound together by the periosteum of the bone, which becomes continuous with the perichondrium of the cartilage.

## ARTICULATIONS OF THE STERNUM

**MANUBRIOSTERNAL ARTICULATION.** The inferior surface of the manubrium is united with the superior border of the body of the sternum by a fibrocartilaginous disc, which is shaped to conform to the hyaline cartilage-covered bony surfaces. The lateral margins of this symphysis are contiguous with the second sternocostal joints. At times, the center of the disc softens, becomes absorbed, and forms a cavity, thereby assuming the character of a synovial joint. At their articulation site, the manubrium and sternal body usually present a slight anteriorly projecting ridge, called the **sternal angle**. This is generally palpable beneath the skin and serves as an important surface landmark to the clinician. After maturation, this joint becomes ossified in about 10% of individuals (Trotter, 1934).

**XIPHISTERNAL ARTICULATION.** The articulation between the xiphoid process and the inferior border of the sternal body is cartilaginous. Bound by longitudinal fibers anteriorly and posteriorly, this joint is also secured laterally by radiating fibers of the sternocostal ligaments. Generally, the seventh costal cartilage articulates with the sternum at the lateral margins of the xiphisternal junction. By the thirtieth year, the xiphisternal joint has usually become ossified.

**MECHANISM OF THE THORAX.** Each rib possesses its own range of movements, but in combination they allow the respiratory excursions of the thorax. Each rib may be regarded as a lever, the fulcrum of

which is situated immediately lateral to the costotransverse joint so that when the shaft of the rib is elevated, the neck is depressed and *vice versa*. Because there is a disproportion in length of the arms of the lever, a slight movement at the vertebral end of the rib is greatly magnified at the anterior extremity.

The anterior ends of the ribs lie at a more inferior plane than the posterior ends, and thus, when the shaft of the rib is elevated, the anterior extremity is also thrust forward. Because the middle of the shaft of the rib lies at a plane inferior to one passing through the rib's two extremities, the shaft is elevated at the same time as it is thrust forward from the median plane of the thorax (Fig. 5-25). Further, each rib forms the segment of a curve which is greater than that of the rib immediately above, and therefore the elevation of a rib also increases the transverse diameter of the thorax. The modifications of the rib movements at their vertebral ends have already been described (p. 354). Further modifications in their movement result from the attachments of their ventral extremities. It is convenient, therefore, to consider the movements of three different groups of ribs separately according to their anterior attachment: vertebrosteral, vertebrochondral, and vertebral.

**VERTEBROSTERAL RIBS** (Figs. 5-25; 5-26). The **first rib** differs from the others of this group because its attachment to the sternum is rigid. Its head, however, possesses no interarticular ligament, and is therefore somewhat more movable. The first pair of ribs moves with the manubrium as a single piece, the ventral portion being elevated by rotatory movements at the necks of the ribs near the verte-

**Fig. 5-25.** Lateral view of first and seventh ribs in position, showing the movements of the sternum and ribs in A, ordinary expiration; B, quiet inspiration; C, deep inspiration.

bral extremities. In normal quiet respiration, the movement of this arc is practically *nil*. When some movement does occur, the ventral part is raised and carried forward, increasing both diameters of this region of the chest. Movement of the **second rib** is also slight in normal respiration because its anterior extremity is fixed to the manubrium and therefore prevented from moving upward. The sternocostal articulation, however, allows the middle of the body of the second rib to be drawn up, and in this way the transverse thoracic diameter is increased. Elevation of the **third to the sixth ribs** raises and thrusts their anterior extremities forward, the greater part of the movement being effected by rotation of the rib neck. The manubriosternal joint allows the relative positions of the manubrium and the body of the sternum to be adjusted when the anteroposterior thoracic diameter is increased. This movement is soon arrested, however, and the force is then expended in raising the middle part of the shaft of the rib, everting its lower border, and increasing the costochondral angle.

**VERTEBROCHONDRAL RIBS** (Fig. 5-27). The **seventh rib** is included along with the **eighth, ninth, and tenth ribs** in this group because it conforms more closely to their type. Although the movements of these ribs assist in enlarging the thorax for respiratory purposes, they are also concerned in increasing the upper abdominal space for viscera displaced by the action of the diaphragm. The costal cartilages of the sixth through the tenth ribs articulate with one another, so that each pushes up the costal cartilage above it, the final thrust being directed to pushing

**FIG. 5-26.** Diagram showing the axes of movement (AB and CD) of a vertebrocostal rib. The interrupted lines indicate the position of the rib during inspiration.

**FIG. 5-27.** Diagram showing the axis of movement (AB) of a vertebrochondral rib. The interrupted lines indicate the position of the rib during inspiration.

forward and upward the lower end of the body of the sternum. The amount of elevation of the anterior extremities is limited because of the very slight rotation of the rib neck. Elevation of the rib shaft is accompanied by an outward and backward movement. The outward movement everts the anterior end of the rib and widens the infrasternal angle, whereas the backward movement pulls back the anterior extremity and counteracts the forward thrust due to its elevation; this latter is most noticeable in the lower ribs, which are the shortest. The total result is a considerable increase in the transverse, and a diminution in the median anteroposterior, diameter of the upper part of the abdomen. At the same time, however, the lateral anteroposterior diameters of the abdomen are increased.

**VERTEBRAL RIBS.** Because the **eleventh and twelfth ribs** have free anterior extremities and only costovertebral articulations with no intra-articular ligaments, they are capable of slight movements in all directions. When the other ribs are elevated, these are depressed and fixed by muscles to form stable points of action for the diaphragm.

#### **LUMBOSACRAL, SACROCOCCYGEAL, AND INTERCOCCYGEAL JOINTS**

**LUMBOSACRAL JOINT.** The ligaments that articulate the fifth lumbar vertebra with the sacrum are similar to those that join any other two adjacent vertebrae in the spinal column. These include: (1) the continuation

caudally of the anterior and posterior longitudinal ligaments; (2) a thick intervertebral disc, which connects the body of the fifth lumbar to that of the first sacral vertebra; (3) *ligamenta flava*, which unite the laminae of the fifth lumbar vertebra with those of the first sacral vertebra; (4) *articular capsules*, which surround the articular processes; and (5) *interspinal and supraspinal ligaments*.

Additionally, on each side, the **iliolumbar ligament** connects the pelvis with the vertebral column.

The **iliolumbar ligament** (Fig. 5-29) is attached to the lateral tip and to the anterior and inferior aspects of the transverse process of the fifth lumbar vertebra. It radiates as it passes laterally and is attached by two main bands to the pelvis. The more inferior band, called the **lumbosacral ligament**, courses to the base of the sacrum and blends with the anterior sacroiliac ligament. The more superior band is attached to the crest of the ilium immediately anterior to the sacroiliac articulation, and is continuous with the thoracolumbar fascia. The psoas major muscle lies anterior to the iliolumbar ligament, while the muscles occupying the vertebral groove are posterior to it. The quadratus lumborum, which partially arises from the ligament, extends superiorly.

**SACROCCYGEAL JOINT.** The sacroccygeal joint is a slightly movable symphysis interposed between the inferiorly directed, oval apex of the sacrum and the cranially oriented base of the coccyx. Between the bones is a fibrocartilaginous disc, but at a more advanced age, the joint may become ankylosed. The sacroccygeal joint is homologous with those between the bodies of the vertebrae, and is secured by similar ligaments.

**Ligaments.** The ligaments at the sacroccygeal joint are:

- Ventral sacroccygeal
- Dorsal sacroccygeal
- Lateral sacroccygeal
- Disc of fibrocartilage
- Interarticular

The **ventral sacroccygeal ligament** consists of a few irregular fibers that descend from the ventral surface of the sacrum to that of the coccyx, blending with the periosteum. This ligament forms a caudal extension of the anterior longitudinal ligament.

The **dorsal sacroccygeal ligament** is a flat band that arises from the margin of the distal orifice of the sacral canal, and descends to be inserted into the dorsal surface of the coccyx. This ligament completes the distal part of the sacral canal and is divisible into a short **deep portion**, which is a direct continuation of the posterior longitudinal ligament of the spinal column, and a longer **superficial part**. The gluteus maximus muscle overlies the ligament dorsally.

The **lateral sacroccygeal ligament** is found on each side and, similar to the intertransverse ligaments, connects the transverse process of the first coccygeal vertebra to the lower lateral angle of the sacrum. With these two bones it completes the foramen for the fifth sacral nerve.

A **disc of fibrocartilage** is interposed between the contiguous surfaces of the sacrum and coccyx. It is oval in shape and measures about 2 cm in diameter. This disc differs from those between the bodies of the vertebrae because it is thinner and its central part is firmer in texture. It is somewhat thicker ventrally and dorsally than at the sides. Occasionally the coccyx is freely movable on the sacrum, especially during pregnancy, and in these instances a synovial membrane is present.

The **intercornual ligaments** are thin fibrous bands that unite the cornua of the coccyx with the sacral horns.

**INTERCOCCYGEAL JOINTS.** The different segments of the coccyx are interconnected by the extension distally of the ventral and dorsal sacroccygeal ligaments. In younger subjects, thin annular discs of fibrocartilage are interposed between the coccygeal segments. In the adult male, all the segments become ossified together at a comparatively early period, but in the female this does not commonly occur until a later period of life.

**MOVEMENTS.** The movements that take place between the sacrum and coccyx, and between the different pieces of the latter bone, are quite limited and simply forward and backward in direction. During defecation and parturition, the coccyx is pushed backward.

**ARTERIES AND NERVES.** The lumbosacral, sacroccygeal, and intercoccygeal joints are supplied by the iliolumbar, middle sacral, and lateral sacral arteries. The nerve supply is derived from sensory branches of the corresponding segmental spinal nerves.

## ARTICULATIONS OF THE PELVIS

The ligaments connecting the bones of the pelvis with each other may be divided into three groups: (1) those connecting the sacrum and ilium; (2) two accessory ligaments passing between the sacrum and ischium; and (3) those between the two pubic bones.

**SACROILIAC JOINT** (Figs. 5-28 to 5-30; 5-32). The sacroiliac joint is a synovial joint that permits little movement. It connects the auricular surfaces of the sacrum and the ilium, and the interfacing borders of each bone are covered with cartilage. Covering the sacral surface is a layer of hyaline cartilage, which is thicker in depth than the fibrocartilage layer overlying the articular surface of the ilium. The joint surfaces are irregularly shaped, and the interconnecting bones fit snugly, thus restricting movement and buttressing the weight-bearing function of the joint. In advanced life, the cavity of the joint may be reduced in size or even nonexistent because of fibrous adhesions and synostosis.

This seems especially true in males. Surrounding the articular surfaces is a fibrous **articular capsule**.

**Ligaments.** The bones are held together by the following ligaments:

Ventral sacroiliac  
Dorsal sacroiliac  
Interosseous

The **ventral sacroiliac ligament** (Fig. 5-29) consists of numerous thin fibrous bands which unite the base and lateral part of the sacrum to the margin of the auricular surface of the ilium and to the preauricular sulcus. It blends with the periosteum on the pelvic surface and reaches the arcuate line.

The **dorsal sacroiliac ligament** (Fig. 5-30) is quite strong and forms an important band of union between the sacrum and ilium. It is situated posteriorly in a deep depression between the two bones and consists of numerous fasciculi which course in various directions. The deeper part is called the **short posterior sacroiliac ligament**, and it is

**FIG. 5-28.** A coronal section through the pelvis showing the sacroiliac joint through the anterior sacral segment. Note the interosseous sacroiliac ligament filling the cleft above and behind the joint cavity. (From Benninghoff and Goerttler, 1975.)

**Fig. 5-29.** The joints and ligaments of the right half of the pelvis. Anterior superior aspect.

nearly horizontal in direction, passing inferiorly and medially from the first and second transverse tubercles on the dorsum of the sacrum to the tuberosity of the ilium. The more superficial portion is oriented longitudinally and is called the **long posterior sacroiliac ligament**. It partially covers the short ligament and attaches above to the posterior

superior iliac spine and to the second, third, and fourth articular tubercles of the sacrum. Descending a bit obliquely, it becomes continuous with the sacrotuberous ligament.

The **interosseous sacroiliac ligament** (Fig. 5-28) is the strongest of the ligamentous connections between the two bones. It lies deep to the dorsal sacroiliac ligament, and con-

**FIG. 5-30.** The joints and ligaments of the right side of the pelvis. Posterior aspect.

sists of a series of short, strong fibers connecting the tuberosities of the sacrum and ilium. By filling the narrow cleft above and behind the articular surfaces, its more superficial fibers blend with those of the short posterior sacroiliac ligament.

**TWO ACCESSORY LIGAMENTS PASSING BETWEEN THE SACRUM AND THE ISCHIUM.** The lower posterolateral wall of the pelvis is not enclosed by bone. Instead two important accessory ligaments attach from the sacrum and lower ilium to the ischium, converting

the large sciatic notch into the **greater and lesser sciatic foramina**. The two ligaments are:

Sacrotuberous  
Sacrospinous

The **sacrotuberous ligament** (Figs. 5-29; 5-30) is a broad, flat, fan-shaped complex of fibers attaching above to the posterior superior and posterior inferior iliac spines, the fourth and fifth transverse tubercles of the sacrum, and the caudal part of the lateral margin of the sacrum and upper coccyx. Passing obliquely downward and laterally, the ligament is fixed to the medial margin of the ischial tuberosity. Before the converging fibers reach the tuberosity they first form a strong, thick band, and then again fan out as they attach to the tuberosity. Some of its fibers are prolonged forward along the ramus of the ischium as the **falciform process**, to which the obturator fascia is attached. The caudal border of the ligament is directly continuous with the tendon of origin of the biceps femoris muscle, and may be considered to be the proximal end of this tendon, interrupted in its projection by the tuberosity of the ischium. Many of the proximal fibers of the sacrotuberous ligament blend with those of the long posterior sacroiliac ligament. The *posterior surface* of the sacrotuberous ligament gives origin to the gluteus maximus muscle; its *anterior surface* is, in part, united to the sacrospinous ligament and, in part, gives origin to some fibers of the piriformis muscle.

The **sacrospinous ligament** (Figs. 5-29; 5-30) is thin and triangular and is attached by its broad base to the lateral margins of the sacrum and coccyx, where its fibers are intermingled with those of the intrapelvic surface of the sacrotuberous ligament. Its apex extends laterally to the spine of the ischium. The *anterior surface* of the sacrospinous ligament gives attachment to the coccygeus muscle, while *posteriorly*, it is covered by the sacrotuberous ligament and crossed by the internal pudendal vessels and nerve. The sacrospinous ligament transforms the sciatic notch into the **greater and lesser sciatic foramina**, its *superior border* forming the lower boundary of the greater sciatic foramen, and its *inferior border*, part of the upper margin of the lesser sciatic foramen.

**GREATER AND LESSER SCIATIC FORAMINA** (Figs. 5-28 to 5-30). The **greater sciatic foramen** is bounded *in front* and *above* by the posterior border of the hip bone, *behind* by the sacrotuberous ligament, and *below* by the sacrospinous ligament. It is partially occupied by the piriformis muscle, which leaves the pelvis through it. Above this muscle, the superior gluteal vessels and nerve emerge from the pelvis, and below it, the inferior gluteal vessels and nerve, the internal pudendal vessels and nerve, the sciatic and posterior femoral cutaneous nerves, and the nerves to the obturator internus and quadratus femoris all make their exit from the pelvis. The **lesser sciatic foramen** is bounded *in front* by the tuberosity and body of the ischium, *above* by the spine of the ischium and sacrospinous ligament, and *behind* by the sacrotuberous ligament. It transmits the tendon of the obturator internus muscle, its nerve, and the internal pudendal vessels and nerve.

**PUBIC SYMPHYSIS** (Fig. 5-31). This cartilaginous articulation in the midline between the pubic bones is a slightly movable joint. Interconnecting the two oval, articular symphyseal surfaces of the bones is a fibrocartilaginous disc. In the female the joint is somewhat shorter and broader than in the male.

**Ligaments.** The ligaments of the pubic symphysis are:

Superior pubic  
Arcuate pubic  
Interpubic disc

The **superior pubic ligament** (Fig. 5-31) connects the two pubic bones superiorly and extends laterally as far as the pubic tubercles. From its yellowish fibers arises the rectus abdominis muscle.

The **arcuate pubic ligament** (Fig. 5-31) is a thick, triangular band of ligamentous fibers connecting the two pubic bones inferiorly, and forming the boundary of the pubic arch. Above, it is blended with the interpubic fibrocartilaginous disc. Laterally, it is attached to the inferior rami of the pubic bones, and its inferior free border is separated from the fascia of the urogenital diaphragm by an opening through which the deep dorsal vein of the penis or clitoris passes into the pelvis.

The **interpubic disc** of fibrocartilage is interposed between the adjacent surfaces of the pubic bones (Fig. 5-31). Both surfaces are covered by a thin layer of hyaline cartilage firmly joined to the bone. A series of nipple-like processes snugly fits into corresponding

Fig. 5-31. Symphysis pubis exposed by a coronal section.

depressions on the osseous surfaces. The fibrocartilaginous disc intervening between the opposed cartilage-covered surfaces varies in width, but usually is thicker in females than in males. Frequently, a cavity is seen in the upper posterior part of the joint (shown as a fine line in Fig. 5-31). This cavity probably is formed by the softening and absorption of fibrocartilage, since it rarely appears before the tenth year of life and is not lined by synovial membrane. The disc is strengthened anteriorly by decussating fibers which pass obliquely from one bone to the other and interlace with fibers of the aponeuroses of the external oblique muscles and the medial tendons of origin of the rectus abdominis muscles.

**MECHANISM OF THE PELVIS.** The pelvic girdle supports and protects the contained viscera; in addition, it affords surfaces for the attachment of trunk and lower limb muscles. Because of our upright posture, the most important mechanical function of the human pelvis is to transmit the weight of the trunk and upper limbs to the lower limbs. From the last lumbar vertebra, the weight of the upper body is transmitted through the sacrum to the ilium and then to the head of the femur to the acetabulum.

The pelvic girdle may be divided into a posterior

and an anterior arch by a vertical plane passing through the acetabular cavities. The *posterior arch* is the one chiefly concerned in the transmission of weight. Its essential parts are the upper three sacral vertebrae and two strong pillars of bone extending from the sacroiliac joints to the acetabular cavities. The *anterior arch* is formed by the bodies of the pubic bones and their superior rami, which articulate in the middle of the arch at the symphysis pubis.

Thus, for the diffusion of weight, each acetabular cavity is strengthened not only by the superior ramus of the pubis, but also by the upper portion of the body of the ramus. The sacroiliac joints, interposed between the sacrum and the ilia, lessen the concussion to rapid changes in the distribution of weight. Additionally, the symphysis pubis in the center of the anterior arch helps to dissipate sudden weight displacements.

The sacrum forms the summit of the posterior arch. The weight transmitted from the upper part of the body is received by the sacrum at the lumbosacral articulation and, theoretically, is transmitted by two components in different directions. One component of the force is expended in driving the sacrum downward and backward between the iliac bones, while the other thrusts the upper end of the sacrum downward and forward toward the pelvic cavity.

The movements of the sacrum are regulated by its form. Viewed in its entirety, it presents the shape of a wedge with its base oriented upward and forward. The first component of the force is therefore acting against the resistance of the wedge, and its tend-

ency to separate the iliac bones is resisted by the sacroiliac and iliolumbar ligaments and by the ligaments of the pubic symphysis.

If a series of coronal sections of the sacroiliac joints is made, it is possible to divide the articular portion of the sacrum into three segments, anterior, middle, and posterior. In the **first or anterior segment** (Fig. 5-32, A), which involves the first sacral vertebra, the articular surfaces are nearly parallel, although the distance between their posterior margins is slightly greater than that between their anterior margins. This segment therefore presents a slight wedge shape with the truncated apex downward and forward. The **second or middle segment**

(Fig. 5-32, B) is a narrow band across the centers of the articulations. Its posterior width is distinctly greater than its anterior, so that the segment is more definitely wedge-shaped, the truncated apex being again directed downward and forward. In the center of each sacral articular surface is seen a marked concavity into which a corresponding convexity of the iliac articular surface fits, forming an interlocking mechanism. In the **third or posterior segment** (Fig. 5-32, C), the anterior width is greater than the posterior, so that the wedge form is the reverse of those of the other segments, and the truncated apex is directed backward and upward. The sacral articular surfaces are only slightly concave.

**FIG. 5-32.** Coronal sections through the sacroiliac joint: A, through the anterior or first sacral segment; B, through the middle or second sacral segment; C, through the posterior or third sacral segment.

Dislocation downward and forward of the sacrum by the second component of the force applied to it is prevented, therefore, by the second or middle segment, which interposes the resistance of its wedge shape and that of the interlocking mechanism on its surfaces. As a result, a rotatory movement is produced by which the anterior or first segment is tilted downward and the posterior or third segment is tilted upward. The axis of this rotation passes through the posterior part of the second or middle segment. Movement of the anterior or first segment is slightly limited by its wedge form, but chiefly by the dorsal and interosseous sacroiliac ligaments. Similarly, movement of the posterior or third segment is checked to a slight extent by its wedge form, but principally by the sacrotuberous and sacrospinous ligaments. In all these movements the effect of the sacroiliac and ilio-lumbar ligaments and the ligaments of the symphysis pubis in resisting the separation of the iliac bones must be recognized.

During pregnancy the pelvic joints become somewhat more mobile because of the softening of the symphyseal cartilage and the relaxation of the ligaments. Thus, the degree of sacral rotation allowable increases slightly, and during childbirth this also may afford a slight increase in the diameter of the pelvis. When the fetus is being expelled, force is applied from within the pelvis to the sacrum. Significant upward dislocation, however, is prevented by the interlocking mechanism of the second or middle segment. As the fetal head passes the anterior segment, the latter is rotated upward, enlarging slightly the dorsoventral diameter of the pelvic inlet. When the head reaches the posterior segment of the sacrum, this also is pressed upward against the resistance of its wedge, the movement being possible only by the laxity of the joints and the stretching of the sacrotuberous and sacrospinous ligaments.

## Articulations of the Upper Extremity

The **shoulder girdle** is a term referring to the means by which the upper limb is appended to the trunk. It consists of the scapulae and clavicles, and anteriorly the girdle is completed by the manubrium of the sternum, to which the clavicles are joined at the **sternoclavicular joints**. Posteriorly, the scapulae do not articulate with the axial skeleton, but are attached to ribs and vertebral column by muscles. Laterally, the scapula is attached on each side to the clavicle at the **acromioclavicular joint**. The humerus articulates with the scapula at the **shoulder joint** and is also joined below to the bones of the forearm at the **elbow joint**. The **radioulnar joints** lend stability to the forearm and af-

ford the hand increased mobility. The **wrist joint** interposes the forearm and the hand, and between the carpal bones of the wrist are found the **intercarpal joints**. The skeleton of the hand consists of metacarpal bones which articulate (1) proximally, with the carpal bones at the **carpometacarpal joints**, (2) with each other by means of **intermetacarpal joints**, and (3) distally, with the phalanges of the digits at the **metacarpophalangeal joints**. Finally, the segments of the fingers and thumb articulate at the **interphalangeal joints**.

## SHOULDER GIRDLE

The shoulder girdle significantly increases the mobility of the upper limb. Interconnecting its structures are the sternoclavicular and acromioclavicular joints.

**STERNOCLAVICULAR JOINT.** The sternoclavicular joint (Fig. 5-33) is a double gliding joint. Entering into its formation are the sternal end of the clavicle, the superior and lateral part of the manubrium sterni at the clavicular notch, and the cartilage of the first rib. The articular surface of the clavicle is much larger than that of the sternum, and it is invested with a layer of fibrocartilage which is thicker than that on the sternum. The bones are not well adapted for articulation and actually are nowhere in contact, being separated completely by an articular disc.

**Ligaments.** The ligaments of this joint are:

- Articular capsule
- Anterior sternoclavicular
- Posterior sternoclavicular
- Interclavicular
- Costoclavicular
- Articular disc

The **articular capsule** surrounds the articulation and varies in thickness and strength. In front and behind, it is of considerable thickness and is reinforced by the anterior and posterior sternoclavicular ligaments. Superiorly, the capsule is strengthened somewhat by the interclavicular ligament, but inferiorly, it is thin and partakes more of the character of areolar tissue.

The **anterior sternoclavicular ligament** (Fig. 5-33) is a broad band of fibers covering the anterior surface of the joint. It is at-

Fig. 5-33. The sternoclavicular joints. Anterior aspect.

tached above to the upper and front part of the sternal end of the clavicle. Passing obliquely downward and medialward, the ligament is attached below to the front and upper part of the manubrium sterni. This ligament is covered by the sternal portion of the sternocleidomastoid muscle and behind it lies the articular capsule, the articular disc, and the two synovial membranes.

The **posterior sternoclavicular ligament** is a band of fibers similar to the anterior ligament, but covering the dorsal surface of the articulation. It is attached to the superior part of the sternal end of the clavicle, and passing obliquely medialward, it is fixed below to the back of the upper part of the manubrium sterni. Adjacent to the ligament anteriorly are the articular disc and synovial membranes, while posteriorly lie the sternohyoid and sternothyroid muscles.

The **interclavicular ligament** (Fig. 5-33) is a flattened band of varying size in different individuals which considerably strengthens the superior part of the capsule. It passes in a curved manner from the upper part of the sternal end of one clavicle to that of the other, and is also attached to the superior margin of the sternum, forming the floor of the jugular notch. Ventral to the ligament are the sternocleidomastoid muscles and the skin, while dorsal to it are the sternohyoids.

The **costoclavicular ligament** (Fig. 5-33) is a short, flat, strong and rhomboid-shaped band located outside the capsule, lateral to the joint. It is attached below to the upper and medial part of the cartilage of the first rib, and ascends obliquely backward and

laterally to the costal tuberosity on the inferior surface of the clavicle. Immediately anterior to the ligament is the tendon of origin of the subclavius muscle, while behind it courses the subclavian vein.

The **articular disc** is flat, nearly circular, and interposed between the articulating surfaces of the sternum and clavicle. Above, it is attached to the dorsal superior border of the articular surface of the clavicle and, below, to the cartilage of the first rib near its junction with the sternum. By the rest of its circumference the disc adheres to the interclavicular and anterior and posterior sternoclavicular ligaments. It is thicker near its rounded margin, especially its upper and posterior part, than at its center. The disc divides the joint into two cavities, each of which is furnished with a synovial membrane.

**Synovial Membranes.** The more lateral of the two synovial cavities is lined by a membrane that is reflected from the sternal end of the clavicle, over the adjacent surface of the articular disc, and around the margin of the facet on the cartilage of the first rib. The synovial membrane lining the more medial cavity is attached to the margin of the articular surface of the sternum and clothes the adjacent surface of the articular disc. The lateral cavity is often a bit larger than the medial and its capsular covering somewhat looser. The two cavities may communicate by way of a perforation in the articular disc.

**Arteries and Nerves.** The arteries supplying twigs to the sternoclavicular joint include: (1) the internal thoracic (from subclavian), (2) the supra-scapular (from thyrocervical trunk), and (3) the

supreme thoracic or clavicular branch of the thoracoacromial artery (from subclavian). The nerves to the sternoclavicular joint are derived from the more medial of the supraclavicular nerves, and a branch from the nerve to the subclavius muscle.

**Movements.** The sternoclavicular joint allows limited movement in nearly every direction. When movements occur in this joint, the clavicle carries the scapula with it, and in turn the scapula glides over the surface of the thorax. This joint therefore forms the center from which all movements of the supporting arch of the shoulder originate, and is the only articulation of the shoulder girdle with the trunk.

*Elevation and depression* of the shoulder take place between the clavicle and the articular disc, the bone rotating upon the ligament on an axis drawn through its own articular facet. When the shoulder is *moved forward (protraction)* or *backward (retraction)*, the clavicle and the articular disc roll to and fro on the articular surface of the sternum, revolving with a sliding movement around an axis drawn nearly vertically through the sternum. In circumduction at the shoulder joint, an action that combines the other movements, the clavicle revolves upon the articular disc, which, with the clavicle, rolls upon the

sternum. Elevation of the shoulder is limited principally by the costoclavicular ligament, and depression, by the interclavicular ligament and articular disc.

The **muscles** that *elevate the shoulder* are the cranial fibers of the trapezius, the levator scapulae, and the clavicular head of the sternocleidomastoid, assisted to a certain extent by the rhomboids. *Depression of the shoulder* is principally effected by gravity assisted by the subclavius, pectoralis minor, and caudal fibers of the trapezius. The shoulder is *protracted* (drawn forward) by the serratus anterior and pectoralis minor, and it is *retracted* (drawn backward) by the rhomboids and the middle and caudal fibers of the trapezius.

**ACROMIOCLAVICULAR JOINT.** The acromioclavicular joint (Figs. 5-34; 5-35) is a small synovial joint of the plane or gliding type between the acromial end of the clavicle and the medial margin of the acromion of the scapula. Both bony surfaces, covered with fibrocartilage, slope downward, and the clavicle has a tendency to override the acromion.

**Fig. 5-34.** Roentgenogram of adult shoulder, 1, acromion; 2, acromioclavicular joint. The lower arrow indicates the inferior angle of the scapula, the upper arrow the greater tuberosity of the humerus. Note that the shadow of the head of the humerus overlaps the shadow of the acromial angle and a part of the glenoid cavity.

FIG. 5-35. The left shoulder and acromioclavicular joints viewed from the anterior aspect.

**Ligaments.** The joint is surrounded by an articular capsule and its ligaments are:

- Articular capsule
- Acromioclavicular
- Articular disc
- Coracoclavicular
  - Trapezoid ligament
  - Conoid ligament

The **articular capsule** completely surrounds the articular margins and is strengthened above by the acromioclavicular ligament. It is somewhat lax so that the clavicle is not bound tightly to the acromion.

The **acromioclavicular ligament** (Fig. 5-35) is a quadrilateral band of parallel fibers that strengthens the superior part of the articular capsule, extending between the acromial end of the clavicle and the adjoining part of the acromion. It interlaces with the aponeuroses of the trapezius and deltoid and is in contact with the articular disc when this is present. Inferiorly, this ligament is thinner and is adjacent to the tendon of the supraspinatus muscle.

The **articular disc**, which is occasionally

present, only partially separates the articular surfaces and occupies the superior part of the articulation, where it attaches to the capsule. More rarely, it completely divides the joint into two cavities. There is usually only one synovial membrane in this articulation, but when a complete articular disc is present, there are two.

The **coracoclavicular ligament** (Fig. 5-35) connects the clavicle with the coracoid process of the scapula. Although placed at some distance medial to this articulation, it forms the most powerful union between the scapula and the clavicle. It consists of two parts which, because of their shapes, are called the **trapezoid** and **conoid ligaments**. These two ligamentous bands are separated by a bursa near their attachment anteriorly and medially along the coracoid process.

The **trapezoid ligament**, placed anterolaterally, is broad, thin, and quadrilateral, and it courses obliquely between the coracoid process and the clavicle. It is attached below to the superior surface of the coracoid process and above to the oblique ridge on the inferior surface of the clavicle. Directed

nearly horizontally, the ventral border of the ligament is free, while its dorsal border is joined with the conoid ligament, the two forming an angle by their junction which projects backward.

The **conoid ligament** is oriented in a posterior and medial direction. It is a dense band of fibers, conical in form, attached by its apex to a rough impression on the postero-medial edge of the coracoid process, medial to the trapezoid ligament. Its expanded base is directed to the coracoid tuberosity on the inferior surface of the clavicle, and along a short line proceeding medialward from the tubercle. These ligaments are adjacent to the subclavius and deltoid anteriorly, and the trapezius muscle posteriorly.

**Movements.** Two types of movement are permitted between the clavicle and the scapula: (1) a gliding motion of the articular end of the clavicle on the acromion; (2) rotation of the scapula forward and backward upon the clavicle, the extent of which is limited by the coracoclavicular ligament. Forward rotation is limited by the trapezoid ligament, while backward rotation is limited by the conoid.

The acromioclavicular and sternoclavicular joints function cooperatively whenever the scapula changes its position on the posterior chest wall. The acromion is held by the clavicle at a fixed distance from the sternum, and thus, the clavicle serves as the radius of a circle through which the acromion must move. Because the diameter of this circle is greater than that of the curvature of the chest wall, the vertebral border of the scapula would be forced to swing away from the chest when the scapula is moved ventrally. The acromioclavicular joint allows the scapula to adjust its position so that it remains in close contact with the chest.

**INTRINSIC LIGAMENTS OF THE SCAPULA.** The following intrinsic ligaments of the scapula pass between different parts of that bone, and do not interconnect different bones at any joint:

Coracoacromial  
Superior transverse scapular  
Inferior transverse scapular

The **coracoacromial ligament** (Fig. 5-35) is a strong triangular band extending between the coracoid process and the acromion. Its apex is attached to the summit of the acromion just anterior to the articular surface for the clavicle, and its broad base is fixed to the whole length of the lateral border of the coracoid process. This ligament, together with the coracoid process and the acromion,

forms an arch overlying the superior aspect of the head of the humerus. It is related superiorly to the clavicle and inner surface of the deltoid muscle, and inferiorly to the tendon of the supraspinatus with a bursa being interposed. Its lateral border is continuous with a dense connective tissue lamina, which passes deep to the deltoid upon the tendons of the supraspinatus and infraspinatus. The coracoacromial ligament sometimes consists of two marginal bands and a thinner intervening portion, the two bands being attached respectively to the tip and base of the coracoid process, joining together at the acromion. When the pectoralis minor muscle is inserted into the capsule of the shoulder joint instead of into the coracoid process, as occasionally occurs, it passes between these two bands, and the intervening portion of the ligament is then deficient.

The **superior transverse scapular ligament** (Figs. 5-35; 5-36), sometimes referred to as the *suprascapular ligament*, converts the scapular notch into a foramen. It is a thin, flat fasciculus, attached by one end to the base of the coracoid process, and by the other to the upper border of the scapula on its dorsal surface near the medial end of the scapular notch. The ligament is sometimes ossified, thereby forming a bony foramen. The suprascapular nerve courses through the foramen, and the suprascapular vessels cross over the ligament. Medially, some fibers of the inferior belly of the omohyoid muscle attach to the ligament.

The **inferior transverse scapular ligament**, when present, is a weak membranous band stretching from the lateral border of the scapular spine to the margin of the glenoid cavity. It forms an arch under which the suprascapular vessels and nerve enter the infraspinatus fossa.

## SHOULDER JOINT

The **shoulder joint** (Figs. 5-34 to 5-38) is a spheroid or ball-and-socket joint in which an elegant freedom of movement is allowed at some expense to its strength and stability. The bones entering into its formation are the hemispherical head of the humerus and the shallow glenoid cavity of the scapula. Some protection of the joint against displacement is afforded by its ligaments and by the tendons and muscles that surround it. The liga-

**Fig. 5-36.** A frontal section through the head of the left humerus and shoulder joint. Anterior half, viewed from behind.

ments alone, however, do not maintain the joint surfaces in apposition, because when the muscles and tendons are removed, the humerus can be separated to a considerable extent from the glenoid cavity. The *ligamentous* protection supplied by the muscles and tendons effectively limits the degree of movement allowed at the joint. Additional protection superiorly is supplied by the arch formed by the coracoid process, acromion, and coracoacromial ligament. Both articular surfaces are covered with hyaline cartilages, although a small amount of fibrocartilage is seen in the glenoid cavity. The cartilage on the head of the humerus is thicker at the center than at the circumference, the reverse being the case with the articular cartilage of the glenoid cavity. The glenoid cavity is deepened by a fibrocartilaginous rim attached to its bony margin.

**Ligaments.** The ligaments of the shoulder joint are:

- Articular cartilage
- Coracohumeral
- Glenohumeral
- Glenoid labrum
- Transverse humeral

The **articular capsule** (Figs. 5-35 to 5-37) completely encases the joint, being attached *medially* to the circumference of the glenoid cavity beyond the glenoid labrum, reaching the neck of the scapula, as far as the root of the coracoid process. *Laterally*, the capsule is fixed to the anatomical neck of the humerus, approaching the articular cartilage more closely superiorly than inferiorly, because its attachment below extends along the neck of the bone about 10 to 12 mm. It is thicker above and below than at its middle, and is so remarkably loose and lax that it does not keep the bones in contact, allowing them to be separated by as much as 2.5 cm. The looseness of the articular capsule is an important factor in the extreme freedom of movement peculiar to the shoulder joint. The capsule is reinforced *above* by the supraspinatus; *below* by the long head of the triceps; *behind* by the tendons of the infraspinatus and teres minor; and *in front* by the tendon of the subscapularis. In the passage of the tendons of the subscapularis, supraspinatus, infraspinatus, and teres minor over the fibrous capsule to their insertions on the tubercles of the humerus, they blend together with the capsule to form a musculo-

**Fig. 5-37.** Interior of the right shoulder joint. Lateral aspect.

**Fig. 5-38.** Synovial membrane of shoulder joint (distended). Anterior aspect.

tendinous or rotator cuff. The cuff is least complete inferiorly, where the joint is quite weak. There are usually three openings in the capsule. One is anteriorly located below the coracoid process, and establishes a communication between the joint and a bursa beneath the tendon of the subscapularis. The second, which is not constant, lies posteriorly, where an opening sometimes exists between the joint and a bursal sac under the tendon of the infraspinatus. The third is located anterolaterally between the tubercles of the humerus and allows the passage of the long tendon of the biceps brachii muscle.

The **coracohumeral ligament** is a broad band that strengthens the upper part of the capsule (Fig. 5-35). From the lateral border of the root of the coracoid process, it takes a slightly spreading and oblique course laterally to the anterior border of the greater tubercle of the humerus, lateral to the tendon of the long head of the biceps. At its humeral attachment it blends with the tendon of the supraspinatus superficial to it, and with the capsule deep to it (except for its anterior free border, which overlaps the capsule).

The **glenohumeral ligaments** are robust thickenings of the articular capsule over the anterior part of the joint. They are described as three ligaments, but their individuality is sometimes difficult to demonstrate. They may be seen in dissection, however, if the joint is disarticulated (Fig. 5-37), or if the capsule is opened posteriorly and the head of the humerus is removed, allowing the observer to view the inner surface of the anterior capsule from behind. The **superior glenohumeral ligament** is attached to the apex of the glenoid cavity, courses laterally along the medial edge of the biceps tendon (long head), and becomes fixed to a small depression at the top of the lesser tubercle. Separated from the coracohumeral ligament by the biceps tendon, the superior glenohumeral ligament courses between the long head tendon and the tendon of the subscapularis. The **middle glenohumeral ligament** is attached to the medial edge of the glenoid cavity of the scapula and stretches across the joint to the lower part of the lesser tubercle. When there is a communication between the synovial cavity and the subscapular bursa, it is found between the superior and middle ligaments. The **inferior glenohumeral ligament** extends from the inferior edge of the glenoid cavity to the lower part of the anatomical neck of the humerus.

The **transverse humeral ligament** (Fig. 5-38) is a sheet of short transverse fibers passing from the lesser to the greater tubercle of the humerus. It is located on the portion of the bone that lies above the epiphyseal line, and converts the intertubercular groove into a short tunnel for the tendon of the long head of the biceps.

The **glenoidal labrum** is a fibrocartilaginous rim attached around the margin of the glenoid cavity. It is triangular in section, the base being fixed to the circumference of the cavity, while the free edge is thin and sharp. Measuring about 6 mm in depth superiorly and inferiorly, the labrum is somewhat more shallow on the sides of the cavity. It is continuous with the tendon of the long head of the biceps, which gives off two fasciculi to blend with the fibrous tissue of the labrum. It deepens the articular cavity, and protects the edges of the bone (Fig. 5-37).

**Synovial Membrane** (Fig. 5-38). The synovial membrane is attached to the margin of the glenoid cavity and is reflected over the inner surface of the articular capsule. It covers the lower part and sides of the anatomical neck of the humerus as far as the articular cartilage on the humeral head. The tendon of the long head of the biceps passes through the capsule and is enclosed in a tubular sheath of synovial membrane, which descends to it from the summit of the glenoid cavity and continues around the tendon into the intertubercular groove as far as the surgical neck of the humerus (Fig. 5-38). The tendon thus traverses the shoulder joint, but it is not contained within the synovial cavity.

**Bursae Associated with the Shoulder.** A number of clinically important bursae are found in the region of the shoulder joint and separate the bony structures from the surrounding muscles and soft tissues. The **subscapular bursa** is found constantly between the tendon of the subscapularis and the underlying joint capsule. It usually communicates with the synovial cavity through an opening between the superior and middle glenohumeral ligaments in the anterior part of the capsule. The **subdeltoid bursa** is a large bursa between the deep surface of the deltoid muscle and the joint capsule, over the upper and lateral aspect of the humerus. It does not communicate with the synovial cavity. The **subacromial bursa** lies between the deep surface of the acromion and tendon of the supraspinatus muscle overlying the joint capsule. It usually extends under the coracoacromial ligament and frequently is continuous with the subdeltoid bursa. A **subcoracoid bursa** may lie between the coracoid process and the capsule, or it may be an extension from the subacromial bursa. The **coracobrachialis bursa** intervenes between the coracobrachialis and subscapularis muscles, but is inconstant. The **infraspinatus**

**bursa**, between the tendon of the infraspinatus muscle and the capsule, may communicate with the synovial cavity. A subtendinous **bursa of the teres major** is found between that muscle and the long head of the triceps near their insertions on the humerus. **Bursae of the latissimus dorsi** are found both superficial and deep to its tendon of insertion. A **bursa of the pectoralis major** muscle is frequently found between its tendon of insertion and the long head of the biceps muscle. The **subcutaneous acromial bursa** is of considerable size and lies between the skin and the superficial surface of the acromion.

**Muscles.** The shoulder joint is anatomically related to the following muscles: *superior*, the supraspinatus; *inferior*, the long head of the triceps; *anterior*, the subscapularis; *posterior*, the infraspinatus and teres minor. Coursing through the joint and surrounded by the reflected synovial membrane is the long head of the biceps muscle. Finally, the deltoid covers the articulation anteriorly, posteriorly, and laterally.

**Blood Supply and Nerves.** The arteries that supply the shoulder joint from the scapular end include the *suprascapular artery* and the *circumflex scapular* branch of the subscapular artery. From the humeral end of the joint are the *anterior* and *posterior humeral circumflex arteries*.

**Nerves** to the shoulder joint are derived principally from the *axillary nerve* (from posterior cord of brachial plexus), the *suprascapular nerve* (from upper trunk of brachial plexus through junction of fifth and sixth cervical nerves), and the *lateral pectoral nerve* (from lateral cord of brachial plexus). At times a branch may come directly from the posterior cord of the brachial plexus or from the radial nerve (Gardner, 1948).

**Movements.** The *shoulder joint* is capable of every variety of movement: flexion, extension, abduction, adduction, circumduction, and rotation. The humerus is **flexed** (drawn forward) by the clavicular part of the pectoralis major, the anterior fibers of the deltoid, the coracobrachialis, and, when the forearm is flexed, the biceps brachii. When the limb is fully extended posterior to the trunk, the sternocostal portion of the pectoralis major assists in flexing the upper extremity until it reaches the side of the body at the anatomical position. The humerus is **extended** (drawn backward) by the latissimus dorsi, the teres major, the posterior fibers of the deltoid, and, when the forearm is extended, the triceps brachii. **Abduction** of the humerus is achieved by the deltoid and supraspinatus, whereas **adduction** is performed by the subscapularis, pectoralis major, latissimus dorsi, and teres major, and by the weight of the limb. **Lateral rotation** of the humerus occurs by action of the infraspinatus, teres minor, and posterior fibers of the deltoid. **Medial rotation** is accomplished by the subscapularis, latissimus dorsi, teres major, pectoralis major, and anterior fibers of the deltoid.

The *scapula* is capable of being moved superiorly and inferiorly, anteriorly and posteriorly, or, by a combination of these movements, circumducted on the posterior wall of the chest. The muscles that **elevate the scapula** are the superior fibers of the trapezius, the levator scapulae, and the rhomboids. Those that **depress the scapula** are the inferior fibers of the trapezius, the pectoralis minor, and, by way of the clavicle, the subclavius. The scapula is **drawn posteriorly** by the rhomboid and the middle and inferior fibers of the trapezius, and it is **drawn anteriorly** by the serratus anterior and pectoralis minor, assisted, when the arm is fixed, by the pectoralis major. This mobility of the scapula is considerable, and greatly assists the movements of the upper limb at the shoulder joint.

Raising of the arm above the head, either anterior to the trunk as in flexion or lateral to the trunk as in abduction, is brought about by a combined action at the shoulder joint and rotation of the scapula on the chest wall. Although it is customary to separate this movement into two parts, i.e., the elevation of the upper limb 90° to the horizontal (due to movement at the shoulder joint) and the continued raising of the arm overhead from 90° to 180° and beyond (due to rotation of the scapula), such a differentiation is artificial. In fact, during practically all of both parts of this movement, the ratio of motion in the two articulations is two parts glenohumeral to one part scapulohoracic. If motion in the glenohumeral articulation is destroyed by ankylosis, only one-third of the whole movement, i.e., 60° of the 180°, will be retained as the compensatory motion of the scapulohoracic articulation.

**Special Anatomical Features.** The most striking peculiarities of the shoulder joint are: (1) the large size of the head of the humerus when compared to the depth of the glenoid cavity, even though the cavity is deepened by the glenoidal labrum; (2) the looseness of the capsule of the joint; (3) the intimate relationship of the capsule with the muscles attached to the head of the humerus; (4) the peculiar association of the tendon of the long head of the biceps brachii with the joint.

It is in consequence of the *relative sizes of the two articular surfaces and the looseness of the articular capsule* that the joint enjoys such free movement in all directions. The upper limb has considerably increased mobility by the movements of the scapula, which involve the acromioclavicular and sternoclavicular joints as well. These joints are regarded as accessory structures to the shoulder joint. The movements of the scapula are considerable, especially in extreme elevation of the upper limb, a movement best accomplished when the arm is thrown somewhat forward and outward because the margin of the head of the humerus is ovoid and not circular. The greatest diameter of the humeral head is directed downward, medialward, and backward from the intertubercular groove, and the greatest elevation of the arm can be obtained by rolling its

articular surface in the direction of this diameter. When the upper limb is elevated 90° to a right angle from the trunk, the great width of the central portion of the humeral head also allows free horizontal movement. In this movement the arch formed by the acromion, the coracoid process, and the coracoacromial ligament may be conceived as a supplemental articular cavity for the head of the humerus.

The *looseness of the capsule* is such that the humeral head falls away from the scapula about 2.5 cm when the muscles are dissected from around the joint. The articular surfaces of the two bones are held in contact, not so much by the capsule as by the surrounding muscles. This arrangement allows easy movement at the joint, especially when the muscles are not under tension. In all ordinary positions of the joint, the capsule is not stretched, but extreme movements are checked by the tension of appropriate portions of the capsule, as well as by certain ligaments and muscles.

The *intimate union of the tendons* of the supraspinatus, infraspinatus, teres minor, and subscapularis, in the formation with the capsule of a musculotendinous or rotary cuff, converts these muscles into elastic and spontaneously acting ligaments of the joint.

The *peculiar relationship of the tendon of the long head of the biceps brachii to the shoulder joint* appears to serve various purposes: (1) by its action at both the shoulder and elbow, the muscle harmonizes the motion at the two joints, and performs as a muscular ligament in all positions; (2) it strengthens the upper part of the articular cavity and prevents the head of the humerus from being pressed against the acromion when the deltoid contracts, and in this manner fixes the head of the humerus as the center of motion in the glenoid cavity; and (3) by the passage along the intertubercular groove, the tendon assists in steadying the head of the humerus in various other movements of the arm. When the upper limb is raised from the side, it assists the supraspinatus and infraspinatus in rotating the head of the humerus in the glenoid cavity. The long biceps tendon also holds the head of the humerus firmly in contact with the glenoid cavity, and prevents its slipping or being displaced by the action of the latissimus dorsi and pectoralis major, as in climbing and many other movements.

**Clinical Relevance.** Dislocation at the shoulder joint occurs more frequently than at any other joint in the body. It usually involves the dislodgement of the head of the humerus inferiorly in the *subglenoid position*, where the capsule is least protected. At the subglenoid site, the triceps muscle usually prevents the humeral head from pushing backward, and thus secondarily, the bone thrusts anteriorly into a subcoracoid or more rarely a subclavicular site in the axilla. At times, the subglenoid dislocation may in fact be secondarily pushed posteriorly to a subacromial or subspinous site.

Rotation of the scapula is of special importance in ankylosis of the shoulder joint because scapular

mobility allows some control of the humerus, thereby compensating to some extent for the immobility at the shoulder joint.

## ELBOW JOINT

In this description, the elbow joint will be considered as that articulation between the lower end of the humerus and the proximal ends of the ulna and radius. Although it is appreciated that within the capsule of the elbow joint is also located the proximal radioulnar articulation, this latter joint will be considered in the next section with the other radioulnar joints.

The **elbow joint** is a compound ginglymus or hinge joint at which are articulated three bones—the humerus, the radius, and the ulna (Figs. 5-39 to 5-42). The **trochlea** of the humerus fits into the **trochlear notch** of the ulna to form a **humero-ulnar articulation**, and the **capitulum** of the humerus articulates with the slightly cupped proximal surface on the **head** of the radius to form a **humero-radial articulation**. The articular surfaces are bound together by a **capsule**, which surrounds the joint and is thickened medially and laterally into the **ulnar collateral** and the **radial collateral** ligaments.

**Ligaments.** Thus, the ligaments to be considered are:

- Articular capsule
- Ulnar collateral
- Radial collateral

The **articular capsule** completely invests the joint (Figs. 5-40 to 5-42). Its **anterior part** is a thin fibrous layer attached above to the front of the medial epicondyle and to the front of the humerus immediately above the coronoid and radial fossae. Below, it adheres to the anterior surface of the coronoid process of the ulna and to the annular ligament of the proximal radioulnar joint. At the sides, the anterior part of the capsule is continuous with the ulnar and radial collateral ligaments. Its superficial fibers pass obliquely from the medial epicondyle of the humerus to the annular ligament. The middle fibers are directed vertically, and pass from the proximal part of the coronoid fossa of the humerus to insert mainly onto the anterior surface of the coronoid process of the ulna. The deeper fibers course transversely and intersect the others at right an-

**Fig. 5-39.** Anteroposterior roentgenogram of an adult elbow joint. The shadow of the olecranon extends upward to the olecranon fossa and is superimposed on the outline of the trochlea. To the left, the head of the radius approximates the capitulum of the humerus, with the humeroradial gap intervening.

gles. The brachialis muscle covers most of the anterior part of the articular capsule, its deep fibers blending with those of the capsule.

The **posterior part** of the articular capsule is thin and membranous, and consists of transverse and oblique fibers (Fig. 5-42). It is attached *above* to the humerus immediately behind the capitulum and close to the medial margin of the trochlea, to the margins of the olecranon fossa, and to the back of the lateral epicondyle, a short distance from the trochlea. Below, it is fixed to the proximal and lateral margins of the olecranon, to the posterior part of the annular ligament, and to the ulna posterior to the radial notch. The transverse fibers of the capsule form a strong band, which bridges the olecranon fossa. Beneath the band is a pouch of synovial membrane and a fat pad, which project into the upper part of the fossa when the joint is

extended. The capsule is related posteriorly to the tendon of insertion of the triceps brachii and to the anconeus muscle.

The **ulnar collateral ligament** is a thick triangular band consisting of two portions, an anterior and posterior, united by a thinner intermediate portion (Fig. 5-40). The **anterior portion** is directed obliquely forward. It is attached *above* by its apex to the front of the medial epicondyle of the humerus and *below* by its broad base to the medial margin of the coronoid process. The **posterior portion**, also triangular in shape, is attached *above* to the lower and posterior part of the medial epicondyle and *below* to the medial margin of the olecranon. Between these two bands a few intermediate fibers descend from the medial epicondyle to blend with a **transverse band** that stretches between the attachments of the anterior and posterior parts on the olecranon and coronoid process of the ulna. Adjacent to this ligament are the triceps brachii and flexor carpi ulnaris muscles and the ulnar nerve. Its anterior portion gives origin to part of the flexor digitorum superficialis muscle.

The **radial collateral ligament** (Fig. 5-41) is a short, narrow, triangular-shaped fibrous band that is somewhat less distinct than the ulnar collateral ligament. It is attached *above* by its apex to a depression distal to the lateral epicondyle of the humerus and *below* to the annular ligament. Some of its most posterior fibers pass over this ligament to be inserted into the lateral margin of the ulna. It is intimately blended with the origins of the supinator and extensor carpi radialis brevis muscles.

**Synovial Membrane** (Figs. 5-43; 5-44). The synovial membrane extends from the margin of the articular surface of the humerus and lines the coronoid, radial, and olecranon fossae on that bone. It is reflected over the inner surface of the articular capsule and forms a pouch between the radial notch of the ulna, the deep surface of the annular ligament, and the circumference of the head of the radius. A crescentic fold of synovial membrane projects between the radius and ulna into the joint cavity from behind, partially dividing the joint into humeroradial and humeroulnar portions. The synovial membrane projects distal to the annular ligament as the **sacciform recess** (Fig. 5-43).

Between the fibrous capsule and the synovial membrane are three fat pads. The largest, over the olecranon fossa, is pressed into the fossa by the triceps brachii during the flexion. A second, over the

FIG. 5-40. The left elbow joint. Medial aspect.

FIG. 5-42. Sagittal section through the left elbow joint.

coronoid fossa, and a third, over the radial fossa, are pressed by the brachialis into their respective fossae during extension.

**Muscles.** In relationship to the elbow joint are the following muscles: *anteriorly*, the brachialis; *posteriorly*, the triceps brachii and anconeus; *laterally*, the supinator, and the common tendon of origin of the extensor muscles; and *medially*, the common tendon of origin of the flexor muscles, including the flexor carpi ulnaris.

**Blood Supply and Nerves.** The arteries supplying the joint are derived from an anastomosis involving the following *descending vessels*: the radial and middle collateral branches of the profunda brachial artery and the superior and inferior ulnar collateral branches from the brachial artery; as well as the following *ascending vessels*: the anterior and posterior ulnar recurrent branches from the ulnar artery, the interosseous recurrent branch from the posterior interosseous artery, and the radial recurrent branch of the radial artery.

The **nerve supply** to the elbow joint is derived from the *musculocutaneous nerve* by way of its

branch to the brachialis muscle, and from the *radial nerve* by way of its branch to the medial head of the triceps muscle and the branch to the anconeus muscle. Additionally, the *ulnar and median nerves* frequently send filaments to the joint.

**Movements.** The elbow joint comprises three different articular appositions. These are the humeroulnar and humeroradial appositions, and the proximal radioulnar joint. All of these articular surfaces are enveloped by a continuous synovial membrane, and the movements within the entire joint should be studied together. The coordinated movements of flexion or extension of the forearm, with those of pronation or supination of the hand, are ensured by the two being performed at the same joint. This coordination is essential for the accuracy of the various minute movements of the hand.

The portion of the joint between the humerus and ulna is a simple hinge joint, and allows movements of flexion and extension only. Owing to the obliquity of the trochlea of the humerus, this movement does not take place in the anteroposterior plane of the humeral shaft. When the forearm is extended and

**FIG. 5-43.** Synovial membrane of the left elbow joint. Anterior aspect. The articular cavity was distended and the fibrous capsule removed. Observe the sacciform recess protruding distal to the annular ligament.

**FIG. 5-44.** Synovial membrane of the left elbow joint. Posterior aspect of the specimen demonstrated in Figure 5-43. Note the limit to which the synovial cavity extends in the olecranon fossa beyond the bony prominence of the olecranon.

supinated, the arm and forearm are not in the same line. Instead, they form an obtuse angle called the *carrying angle*, so that the hand and forearm are directed somewhat laterally to the central axis of the humerus. During flexion at the elbow joint, however, the forearm comes more into line with the central axis of the arm, enabling the hand to be easily carried to the face. The accurate adaptation of the prominences and depressions of the trochlea of the humerus to the semilunar notch of the ulna prevents any lateral movement at the elbow joint. **Flexion** is produced by the action of the biceps brachii and brachialis, assisted by the brachioradialis and the muscles arising from the medial epicondyle of the humerus. **Extension** of the forearm is performed principally by the triceps brachii and anconeus, and to a minor extent by the extensors of the wrist, the extensor digitorum, and the extensor digiti minimi.

The joint between the head of the radius and the capitulum of the humerus is a gliding joint. The bony surfaces are so shaped that they would constitute a spheroid or ball-and-socket joint and allow movement in all directions, were it not for the annular

ligament by which the head of the radius is bound to the radial notch of the ulna. However, this ligament prevents any separation of the two bones laterally and, in fact, gives the head of the radius its security from dislocation, which would otherwise tend to occur because of the shallowness of the cup-like surface on the head of the radius. Were it not for the annular ligament, the tendon of the biceps brachii would be able to pull the head of the radius out of the joint. The radial head is not in complete contact with the capitulum of the humerus in all positions of the joint, so that in complete extension a part of it can be plainly felt projecting at the back of the articulation. In full flexion, movement of the radial head is somewhat hampered by compression of the surrounding soft parts. Thus, the freest rotatory movement of the radius on the humerus (pronation and supination) takes place with the forearm in semiflexion, when the two articular surfaces are in most intimate contact.

The radius, carrying the hand with it, can be rotated in the proximal radioulnar joint when the forearm is in any degree of flexion, or even if it is fully

extended. The hand is directly articulated only to the lower surface of the radius, and the ulna is excluded from the wrist joint directly by an articular disc. Additionally, the lower end of the ulna, on its lateral side, is firmly bound to the radius in the ulnar notch. Thus, when the head of the radius rotates, it imparts a circular movement to the hand through a considerable arc. This allows supination and pronation of the hand.

### RADIOULNAR JOINTS

The articulations of the radius with the ulna occur at the proximal and distal extremities of the bones by means of synovial joints and along their shafts by means of a fibrous interosseous ligament which firmly unites the two bones in the form of a syndesmosis. Three joints interconnect the bones of the forearm:

- Proximal radioulnar joint
- Middle radioulnar union
- Distal radioulnar joint

**PROXIMAL RADIOULNAR JOINT.** This articulation is a trochoid or pivot joint between the circumference of the head of the radius and the ring formed by the radial notch of the ulna and the *annular ligament*.

**Ligaments.** The **annular ligament** (Figs. 5-45; 5-46) is a strong band of fibers which encircles the head of the radius and retains it in contact with the radial notch of the ulna. It forms about four-fifths of the osseofibrous ring, and is attached to the anterior and posterior margins of the notch. For a short distance distal to the radial notch, a few fibers of the annular ligament actually form a com-

**Fig. 5-45.** Proximal part of the ulna with the annular ligament of the proximal radioulnar joint. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban and Schwarzenberg, Munich, 1980).

**Fig. 5-46.** Annular ligament of the proximal radioulnar joint, superior aspect. The head of the radius has been removed and the bone dislodged from the ligament.

plete fibrous ring. Proximally, the annular ligament blends with the anterior and posterior aspects of the articular capsule of the elbow joint, while from its distal border a thin loose membrane is attached to the neck of the radius. A thick band that extends from the inferior border of the annular ligament below the radial notch to the neck of the radius is known as the **quadrate ligament**. The superficial surface of the annular ligament is strengthened by the radial collateral ligament of the elbow (Fig. 5-41), and affords origin to part of the supinator muscle. Its deep surface is smooth and lined by synovial membrane that is continuous with that of the elbow joint.

**Movements.** The movements allowed in this articulation are limited to rotatory movements of the head of the radius within the ring formed by the annular ligament and the radial notch of the ulna. Rotation of the radius, which moves the thumb from lateral to medial, is called *pronation*; rotation in the opposite direction is *supination*. Supination is performed by the biceps brachii and supinator. Pronation is performed by the pronator teres and pronator quadratus.

**MIDDLE RADIOULNAR UNION.** The shafts of the radius and ulna are held together in syndesmosis by two interosseous ligaments.

**Ligaments.** The ligaments of this union are:

- Interosseous membrane
- Oblique cord

The **interosseous membrane** (Fig. 5-40) is a broad and thin plane of fibrous tissue oriented downward and medially from the entire length of the interosseous crest of the radius to that of the ulna. The lower part of the membrane is attached to the posterior of the two ridges into which the interosseous crest of the radius divides distally. The membrane is deficient proximally, and originates about 2.5 cm below the tuberosity of the radius. It is broader in the middle than at either end, and presents an oval aperture a little above its distal margin for the passage of the anterior interosseous vessels to the back of the forearm. This membrane serves to increase the extent of surface for the attachment of the deep muscles as well as to connect the bones. Between its upper border and the oblique cord is a gap through which the posterior interosseous vessels pass. Although the direction of the fibrous bundles in the membrane is oblique, extending from the radius proximally to the ulna distally, there are two or three bands occasionally found on the dorsal surface which course obliquely in the opposite direction. Anteriorly, the upper three-fourths of the interosseous membrane is related to the flexor pollicis longus on the radial side, and to the flexor digitorum profundus on the ulnar. Lying in the interval between these two muscles are the anterior interosseous vessels and nerve. Over the lower one-fourth of the anterior surface stretches the pronator quadratus. Posteriorly, the interosseous membrane is related to the supinator, abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, and extensor indicis muscles and, near the wrist, with the anterior interosseous artery and posterior interosseous nerve.

The **oblique cord** (Figs. 5-40; 5-42) is a small, flattened band extending inferolaterally from the lateral aspect of the tuberosity of the ulna at the base of the coronoid process to the radius, a little distal to the radial tuberosity. Its fibers run in a direction opposite those of the interosseous membrane. It is sometimes absent.

**DISTAL RADIOULNAR JOINT.** This pivot joint is formed between the convex head of the ulna and the grooved ulnar notch on the lower end of the radius. The articular surfaces are enclosed by a relatively loose articular capsule that is lined by a synovial membrane. The joint is further secured by an articular disc.

**Ligaments.** The articular capsule (Figs. 5-47; 5-48) is composed of transversely oriented bands of fibers attached to the margins of the ulnar notch and to the head of the ulna. Although the anterior and posterior parts of the capsule are somewhat thickened, it is still weak and loosely surrounds the joint. The capsule is lined by a synovial membrane that extends as a pouch upward a short distance between the radius and ulna to form a **sacciform recess**.

The **articular disc** (Fig. 5-49) is triangular in shape, and is placed transversely beneath the head of the ulna, binding the lower ends of the ulna and radius firmly together. Its periphery is thicker than its center, which is occasionally perforated. It is attached by its apex to a depression between the styloid process and the head of the ulna, and by its thin base to the prominent edge of the radius, which separates the ulnar notch from the carpal articular surface. Its margins are united to the ligaments of the wrist joint. Its **proximal surface** is smooth and concave, and articulates with the head of the ulna to form a gliding joint. Its **distal surface** forms part of the wrist joint and articulates with the medial part of the lunate bone and, when the hand is adducted, with the triquetral bone.

**Synovial Membrane** (Fig. 5-49). Both proximal and distal surfaces of the articular disc are covered with a synovial layer. The proximal surface of the disc enters into the radioulnar joint, and the joint cavity that is formed appears L-shaped in longitudinal section. Its synovial membrane extends proximally beyond the articular surfaces of the radius and ulna to form the **sacciform recess**. The distal surface of the disc enters into the formation of the wrist joint, and it is also lined by a synovial membrane.

**Vessels and Nerves.** The arteries to the distal radioulnar joint are derived from the anterior and posterior interosseous arteries. The nerves come from the anterior interosseous branch of the median nerve and the posterior interosseous branch of the radial nerve.

**Movements.** The movements at the distal radioulnar joint consist of rotation of the distal end of the radius around a longitudinal axis that passes through the center of the head of the ulna. When the radius and the attached hand rotate obliquely across the anterior aspect of the ulna, **pronation** of the forearm and hand is the result. The reverse movement results in **supination**, and in the fully supine position, the radius and ulna lie parallel in the forearm. Thus, in pronation and supination the radius rotates around the circumference of a segment of a cone, the axis of which extends from the center of

FIG. 5-47. The ligaments of the left wrist and metacarpus. Palmar aspect.

the head of the radius to the middle of the head of the ulna. In this movement the head of the ulna is stationary, but appears to describe a curve in a direction opposite that taken by the head of the radius.

#### RADIOCARPAL OR WRIST JOINT

The **wrist joint** (Figs. 5-47 to 5-49) is a simple synovial articulation, usually classified as an ellipsoid joint. The parts forming it are the distal end of the radius and lower surface of the articular disc above, and the scaphoid, lunate, and triquetral bones below. The articular surface of the radius and the lower surface of the articular disc form together a transversely elliptical con-

cavity. The superior articular surfaces of the scaphoid, lunate, and triquetral bones form a smooth convex surface that is received into the concavity. The ulna is excluded from the joint by the intervening articular disc. The joint is surrounded by an articular capsule.

**Ligaments.** The ligaments of the wrist include:

- Articular capsule
- Palmar radiocarpal
- Dorsal radiocarpal
- Ulnar collateral
- Radial collateral

The **articular capsule** is lined by a synovial layer; it is extensive and loosely binds

FIG. 5-48. The ligaments of the left wrist. Dorsal aspect.

the joint. The capsule is reinforced by the palmar and dorsal radiocarpal ligaments and the ulnar and radial collateral ligaments, which actually cover the greater part of its external surface.

The **palmar radiocarpal ligament** (Fig. 5-47) is a broad membranous band attached

above to the anterior margin of the lower end of the radius, to its styloid process, and to the palmar aspect of the lower end of the ulna. Its fibers pass downward and medially to be inserted *below* into the palmar surfaces of the scaphoid, lunate, and triquetrum bones, some being continued to the capitate. In

FIG. 5-49. Vertical section through the articulations at the wrist, showing the synovial cavities.

addition to this broad membrane, there is a rounded fasciculus, superficial to the rest, which reaches from the base of the styloid process of the ulna to the lunate and triquetral bones. The ligament is perforated by apertures for the passage of vessels. Its palmar surface is related anteriorly to the tendons of the flexor digitorum profundus and flexor pollicis longus, and posteriorly this ligament is closely adherent to the palmar surface of the articular disc in the distal radioulnar joint.

The **dorsal radiocarpal ligament** is thin and membranous (Fig. 5-48), and it is weaker than the palmar radiocarpal ligament. It is attached above to the posterior border of the lower end of the radius. Its fibers, directed obliquely downward and medially, are fixed below to the dorsal surfaces of the scaphoid, lunate, and triquetral bones, and are continuous with those of the dorsal intercarpal ligaments. Posteriorly, the ligament is related to the extensor tendons of the fingers, while anteriorly, it is blended with the articular disc.

The **ulnar collateral ligament** (Figs. 5-47 to 5-49) is a fan-shaped cord with its apex attached above to the end of the styloid process of the ulna. Below, it divides into two fasciculi, one of which is attached to the medial aspect of the triquetral bone, the other to the pisiform bone and transverse carpal ligament. The tendon of the flexor carpi ulnaris lies anterior to the ligament, while that of the extensor carpi ulnaris lies posterior.

The **radial collateral ligament** (Figs. 5-47 to 5-49) extends from the tip of the styloid process of the radius to the radial side of the scaphoid, with some of its fibers being prolonged to the trapezium and the flexor retinaculum. It is related to the radial artery, as the vessel curves around the lateral aspect of the wrist, separating the ligament from the tendons of the abductor pollicis longus and extensor pollicis brevis.

**Synovial Membrane** (Fig. 5-49). The synovial layer lines the inner surfaces of the ligaments described above, extending from the margin of the lower end of the radius and articular disc to the margins of the articular surfaces of the carpal bones below. It is loose and lax, and presents numerous folds, especially dorsally.

**Vessels and Nerves.** The arteries supplying the joint are branches from the anterior interosseous ar-

tery as well as palmar and dorsal carpal branches of the radial and ulnar, the palmar and dorsal metacarpals, and some ascending branches from the deep palmar arch. The nerves to the wrist joint are derived from all three principal nerves of the upper extremity. These are the anterior interosseous branch of the median, the posterior interosseous branch of the radial, and the dorsal and deep branches of the ulnar.

**Movements.** The movements permitted in this joint are flexion, extension, abduction, adduction, and circumduction. They will be described with those of the carpus, with which they are combined. The wrist joint is covered in front by the flexor tendons and dorsally by the extensor tendons.

## INTERCARPAL JOINTS

The intercarpal joints are articulations between the carpal bones and are subdivided into three groups: (1) the joints between the bones of the **proximal row**, that is, the joints connecting the scaphoid, lunate, and triquetral bones, and the articulation of the pisiform bone; (2) the joints between the bones of the **distal row**; and (3) the transverse articulation between the two rows of carpal bones called the **midcarpal joint**.

**INTERCARPAL JOINTS OF THE PROXIMAL ROW: SCAPHOID, LUNATE, AND TRIQUETRAL.** These are gliding joints, and the scaphoid, lunate, and triquetral bones are interconnected by dorsal, palmar, and interosseous ligaments.

**Ligaments.** The two **dorsal intercarpal ligaments** are placed transversely behind the bones of the first row. They connect the scaphoid and lunate, and the lunate and triquetral bones.

The two **palmar intercarpal ligaments** interconnect the scaphoid and lunate, and the lunate and triquetral bones on the anterior aspect of the carpus. They are not so strong as the dorsal intercarpal ligaments, and are placed deep to the flexor tendons and the palmar radiocarpal ligament.

The **interosseous ligaments** (Fig. 5-49) are two narrow bundles, one connecting the lunate and scaphoid bones, and the other joining the lunate and triquetral bones. They are on a level with the proximal surfaces of these bones, and their surfaces are smooth, forming part of the convex articular surface of the wrist joint.

**ARTICULATION OF THE PISIFORM BONE.** The pisiform is articulated to the triquetral bone (the pisotriquetral joint) by a thin **articular**

**capsule**, the synovial cavity of which remains separate and distinct from those of the other carpal bones.

**Ligaments.** Additionally, the pisiform bone is firmly connected proximally by the ulnar collateral and the palmar radiocarpal ligaments (Fig. 5-47). Extending distally from the pisiform bone are two strong fibrous bands, the pisohamate and pisometacarpal ligaments.

The **pisohamate ligament** attaches the pisiform bone to the hook of the hamate bone, while the **pisometacarpal ligament** connects the pisiform to the base of the fifth metacarpal bone (Fig. 5-47). These ligaments transmit the pull of the flexor carpi ulnaris tendon from the pisiform to the distal carpal bones and to the metacarpals, and may be considered as prolongations of that tendon.

**INTERCARPAL JOINTS OF THE DISTAL ROW.** These also are gliding joints, and the four bones of this row are connected by dorsal, palmar, and interosseous ligaments.

**Ligaments.** The **dorsal intercarpal ligaments** are three in number and they extend transversely from one bone to another on the dorsal surface, connecting the trapezium with the trapezoid, the trapezoid with the capitate, and the capitate with the hamate.

The **palmar intercarpal ligaments**, also three in number, have a similar arrangement on the palmar surface.

The **interosseous ligaments** of the distal row are much thicker than those of the proximal row. There are three of these, one is placed between the capitate and the hamate, the second between the capitate and the trapezoid, and the third between the trapezium and trapezoid (Fig. 5-49). The first is much the strongest, and the third is sometimes absent.

**MIDCARPAL JOINT.** The transverse articulation between the scaphoid, lunate, and triquetral bones proximally, and the second row of carpal bones distally, is the important **midcarpal joint**. It is a compound joint and consists of three distinct portions. In the center, the head of the capitate and the proximal angle on the superior surface of the hamate articulate in a deep concavity formed by the scaphoid and lunate to constitute a compound saddle joint. On the radial side of the capitate, the trapezium and trapezoid articulate with the scaphoid, and on the ulnar side the more medial aspect of the hamate articulates with the triquetral bone. These

latter joints are usually considered to be of the plane or gliding type.

**Ligaments.** The midcarpal joint is secured by **palmar and dorsal intercarpal and ulnar and radial carpal collateral ligaments**.

The **palmar intercarpal ligaments** consist of short fibers that pass, for the most part, from the palmar surface of the head of the capitate bone in a radiating manner to the surrounding carpal bones of the proximal row (scaphoid, lunate, and triquetral). Collectively, these ligaments are frequently referred to as the **carpal radiate ligament**.

The **dorsal intercarpal ligaments** consist of short, irregular bundles passing between the dorsal surfaces of the bones of the first and second rows.

The **carpal collateral ligaments** are short; one is placed on the radial, the other on the ulnar side of the carpus. The radial carpal collateral ligament is the stronger and more distinct, and connects the scaphoid and trapezium, while the ulnar carpal collateral ligament joins the triquetral bone and hamate. They are continuous with the collateral ligaments of the wrist joint.

In addition to these ligaments, a slender interosseous band sometimes connects the capitate and the scaphoid.

**Synovial Membrane.** The synovial membrane of the carpus is extensive (Fig. 5-49), and bounds a synovial cavity of irregular shape. The proximal portion of the cavity intervenes between the distal surfaces of the scaphoid, lunate, and triquetral bones and the proximal surfaces of the bones of the second row. It sends *two proximal prolongations*—between the scaphoid and lunate, and the lunate and triquetral bones—and *three distal prolongations*, each of which intervenes between adjacent bones of the second row. The prolongation of the synovial membrane between the trapezium and trapezoid or that between the trapezoid and capitate, because of the absence of interosseous ligaments, is often continuous with the cavity of the carpometacarpal joints. At times this continuity is seen with the joint cavity between the carpal bones and the second, third, fourth, and fifth metacarpal bones; at other times, with that of the second and third metacarpal bones only. In the latter condition the joint between the hamate and the fourth and fifth metacarpal bones has a separate synovial membrane, and is separated from the rest of the carpometacarpal joint cavity by an interosseous ligament (Fig. 5-49). The synovial cavities of the carpometacarpal joints are prolonged for a short distance between the bases of the metacarpal bones. There is a separate synovial membrane between the pisiform and triquetral bones.

**Movements.** The radiocarpal and midcarpal joints involve four articular surfaces: (1) the distal surfaces of the radius and articular disc; (2) the proximal surfaces of the scaphoid, lunate, and triquetral bones, the pisiform having no essential part in the movement of the hand; (3) the S-shaped inferior surfaces of the scaphoid, lunate, and triquetral, and (4) the reciprocal upper surfaces of the carpal bones of the second row. These four surfaces form two principal joints: (1) a proximal, the **wrist joint proper**, and (2) a distal, the **midcarpal joint** (Fig. 5-50).

1. The **wrist joint proper** is an ellipsoid articulation, permitting all movements but rotation to occur. *Flexion* and *extension* are the most free, and of these a greater degree of extension than of flexion of the hand is permitted, because the articulating surfaces extend farther on the dorsal than on the palmar surfaces of the carpal bones. In these movements the carpal bones swing on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. A certain degree of *adduction* (or ulnar flexion) and *abduction* (or radial flexion) is also permitted. A considerably greater degree of adduction can be achieved because of the more proximal position of the styloid process of the ulna, abduction being quite limited by contact of the styloid process of the radius with the trapezium. Abduction and adduction take place about an anteroposterior axis drawn through the capitate bone. Finally, *circumduction* is permitted by the combined and consecutive movements of adduction, extension, abduction, and flexion. Although rotation does not occur at the wrist or midcarpal joints, the effect of rotation is obtained by pronation and supination of the radius on the ulna.

2. At the **midcarpal joint**, flexion, some extension, abduction, and a minor degree of rotation are permitted. In *flexion* and *extension*, the trapezium and trapezoid on the radial side and the hamate on the ulnar side glide forward and backward on the scaphoid and triquetral bones, respectively. Of these two movements, flexion is more freely enjoyed at the midcarpal joint. *Abduction* is accompanied by a slight *rotation* of the head of the capitate and the superior surface of the hamate in the cup-shaped cavity of the scaphoid and lunate.

**Muscles Producing Movements.** The movement of **flexion** of the hand is performed by the flexor carpi radialis, the flexor carpi ulnaris, and the palmaris longus when the fingers are extended. When the fingers are flexed, these muscles are aided by the flexors digitorum superficialis and profundus, flexor pollicis longus, and abductor pollicis longus. **Extension** at the wrist is performed by the extensors carpi radiales longus and brevis and the extensor carpi ulnaris when the fingers are flexed. When the fingers are extended, these muscles are aided by the extensor digitorum, extensor digiti minimi, extensor indicis, and extensor pollicis longus. **Adduction** (ulnar flexion) is performed by the flexor carpi ulnaris and the extensor carpi ulnaris, while **abduction** (ra-

dial flexion) is produced by the extensor carpi radialis longus and brevis and the flexor carpi radialis.

**Vessels and Nerves.** The arteries supplying the intercarpal joints are derived from a palmar and dorsal carpal anastomosis contributed to by (1) the palmar and dorsal carpal branches of the radial and ulnar arteries; (2) carpal recurrent branches of the deep volar arch; and (3) the dorsal carpal branches of the anterior (and posterior) interosseous arteries.

The **nerve supply** to the intercarpal joints comes from carpal branches of the ulnar, median, and posterior interosseous nerves.

## CARPOMETACARPAL JOINTS

The distal surfaces of the distal row of carpal bones interface with the expanded surfaces of the bases of the five metacarpal bones. These five joints may be divided into two sets: (1) carpometacarpal joint of the thumb, and (2) carpometacarpal joints of the four medial fingers.

**CARPOMETACARPAL JOINT OF THE THUMB** (Figs. 5-47 to 5-50). This highly mobile joint

**Fig. 5-50.** Radiograph of adult hand showing the radiocarpal and midcarpal joints along with those of the fingers.

between the base of the first metacarpal bone and the trapezium is the best example in the body of a saddle (or sellar) joint. Its great freedom of movement results from the configuration of its articular surfaces. These are reciprocally saddle-shaped, and surrounded by a capsule that is thick but loose, and passes from the circumference of the base of the first metacarpal bone to the rough edge bounding the articular surface of the trapezium.

**Ligaments.** The capsule is thickest laterally and dorsally, and is reinforced by **lateral (radial), palmar and dorsal (anterior and posterior oblique) carpometacarpal ligaments of the thumb** (Haines, 1944). These ligaments are attached to the trapezium above and pass distally to converge onto the base of the first metacarpal bone.

**Movements.** When the thumb is in the resting anatomical position, its palmar surface is oriented medially and the dorsal surface directed laterally. At the carpometacarpal joint of the thumb, the movements permitted are *flexion* and *extension* in a plane parallel to the palm of the hand, *abduction* and *adduction* in a plane at right angles to the palm, a small degree of *rotation*, *circumduction*, and *opposition*. Flexion is generally accompanied by a slight medial rotation of the first metacarpal, while extension is accompanied by its lateral rotation. Medial rotation occurs because the *dorsal* carpometacarpal ligament tenses the ulnar side of the first metacarpal base during flexion, leaving the radial side of the capsule loose and the metacarpal head free to move. Likewise, during extension, lateral rotation of the metacarpal head results from tension on the ulnar side of the metacarpal base brought about by the *palmar* carpometacarpal ligament, once again allowing the more lax radial side of the metacarpal head freedom to move. Flexion and medial rotation, when combined by a partial abduction of the thumb, results in opposition. It is by the movement of opposition that the tip of the thumb is brought into contact with the palmar surfaces of the slightly flexed tips of the other fingers.

**Muscles Producing Movements.** **Flexion** at the carpometacarpal joint of the thumb is produced by the flexors pollicis brevis and longus, as well as the opponens pollicis. **Extension** of the thumb is effected by the extensors pollicis brevis and longus, as well as the abductor pollicis longus muscle. **Abduction** is produced by the abductors pollicis longus and brevis and to some extent by the opponens pollicis. **Adduction** is carried out by the adductor pollicis. **Opposition** is achieved by the combined action of the flexor pollicis brevis, opponens pollicis, and the abductors which flex, medially rotate, and partially abduct the thumb. In this manner the meta-

carpal bone is rotated to a position in which the palmar surface of the thumb faces the palmar surface of the fingers. After the thumb is in the opposed position, the strong pressure between thumb and fingers is produced by the long flexors. **Circumduction** occurs by the consecutive action of the flexors, abductors, extensors, and adductors.

**Vessels and Nerves.** The arteries to the carpometacarpal joint of the thumb are derived from the radial, the first palmar metacarpal, and the first dorsal metacarpal. The nerves come from branches of the median.

**CARPOMETACARPAL JOINTS OF THE MEDIAL FOUR FINGERS.** The joints between the carpus and the bases of the second, third, fourth, and fifth metacarpal bones are of the plane or gliding type. The bones are united by articular capsules, which are reinforced by dorsal, palmar, and interosseous carpometacarpal ligaments.

**Ligaments.** The **dorsal carpometacarpal ligaments** are the strongest and most distinct, and connect the carpal and metacarpal bones on their dorsal surfaces. The second metacarpal bone receives three fasciculi, one from each of the bones with which it articulates—the trapezium, the trapezoid, and the capitate. The *third metacarpal* receives two, one each from the trapezoid and the capitate; the *fourth* two, one each from the capitate and hamate. The *fifth metacarpal* receives a single fasciculus from the hamate, and this is continuous with a similar ligament on the palmar surface, and forms an incomplete capsule.

The **palmar carpometacarpal ligaments** have an arrangement a bit different from the dorsal. The *second metacarpal* receives one strong band from the trapezium. The *third metacarpal* is attached by three bands to the carpus: a lateral one from the trapezium, situated superficial to the sheath of the tendon of the flexor carpi radialis, an intermediate one from the capitate, and a medial one extending from the hamate. The *fourth* and *fifth metacarpals* receive one palmar ligament each from the hamate. That of the fifth metacarpal is strengthened by fibers extending from the flexor carpi ulnaris tendon.

The **interosseous carpometacarpal ligaments** (Fig. 5-49) consist of short, thick fibers which are limited to two parts of the carpometacarpal articulation. One interosseous ligament connects the distal edge of the trapezium with the lateral margin of the base of

the second metacarpal bone. The other connects the contiguous inferior angles of the capitate and hamate with the adjacent surfaces of the third and fourth metacarpal bones.

**Synovial Membrane.** The synovial cavity is a continuation of that of the intercarpal joints. Occasionally, the joint between the hamate and the fourth and fifth metacarpal bones has a separate synovial cavity, being bound medially by one of the interosseous carpometacarpal ligaments (Fig. 5-49).

**Movements.** The movements permitted at the carpometacarpal articulations of the fingers are limited to slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. The metacarpal bone of the little finger has the greatest range of movement, more than that of the ring finger. The metacarpal bones of the index and middle fingers are almost immovable.

### INTERMETACARPAL JOINTS

The metacarpal bone of the thumb is not articulated with any other metacarpal bone. In contrast, the bases of the second, third, fourth, and fifth metacarpal bones articulate with one another by small surfaces covered with cartilage, and are connected together by dorsal, palmar, and interosseous intermetacarpal ligaments.

**Ligaments.** The **dorsal metacarpal ligaments** are short fibrous bands that pass transversely from bone to bone on the dorsal surface of the bases of the metacarpal bones.

The **palmar metacarpal ligaments** are also short bands, somewhat less defined than the dorsal, which interconnect the bases of adjacent metacarpal bones on their palmar surface.

The **interosseous metacarpal ligaments** interconnect the contiguous surfaces of the bases of the metacarpal bones just distal to their intermetacarpal collateral articular facets.

**Synovial Membranes.** The synovial cavities of the intermetacarpal joints are continuous with those of the carpometacarpal articulations.

### METACARPOPHALANGEAL JOINTS

These articulations are ellipsoid in type and are formed by the reception of the rounded heads of the metacarpal bones into

shallow cavities on the proximal ends, or bases, of the first phalanges. On their dorsal surfaces the metacarpophalangeal joints are covered by the expansions of the extensor tendons, together with some loose areolar tissue which connects the inner aspect of the tendons of the bones. The joints form the prominent proximal knuckles of the clenched fist. On the palmar aspect of these joints, the rounded articular heads of the metacarpal bones are partly divided to appear similar to condyles. The palmar surfaces are crossed by the flexor tendons. The head of the metacarpal bone of the thumb is less convex, wider, and flatter than that of the other fingers; on each side are facets for sesamoid bones.

**Ligaments.** Each metacarpophalangeal joint has a loose articular capsule, and palmar and collateral ligaments. Additionally, the deep transverse metacarpal ligament interconnects the palmar surfaces of the metacarpophalangeal joints of the medial four fingers.

The **palmar ligaments** (Fig. 5-51) are thick, dense, fibrocartilaginous plates placed upon the palmar surfaces of the joints in the intervals between the collateral ligaments, to which they are connected. They are loosely united to the metacarpal bones, but are firmly attached to the bases of the first phalanges. Their **palmar surfaces** are intimately blended with the deep transverse metacarpal ligament, and present grooves for the passage of the flexor tendons. The fibrous sheaths of these tendons are connected to the sides of the grooves. Their **deep surfaces** form parts of the articular facets for the heads of the metacarpal bones.

The **collateral ligaments** (Fig. 5-52) are strong, rounded cords placed on the sides of the joints, reinforcing the articular capsule. Each is attached by its proximal extremity to the **dorsal tubercle** and adjacent depression on the side of the head of the metacarpal bone. The fibers of the ligament then run obliquely across the side of the joint to attach distally on the **palmar aspect** of the base of the proximal phalanx. During flexion of the metacarpal phalangeal joint, the collateral ligaments become tense, thereby preventing much abduction or adduction of the flexed finger.

The **deep transverse metacarpal ligament** (Figs. 5-47; 5-51) consists of a series of three narrow fibrous bands that connect the pal-

**Fig. 5-51.** The metacarpophalangeal and interphalangeal joints of a finger, Palmar aspect.

mar surfaces of the heads of the second, third, fourth, and fifth metacarpal bones. It is blended with the palmar ligaments of the metacarpophalangeal joints, and its palmar surface is concave where the flexor tendons pass. Behind the ligament, the tendons of the interossei pass to their insertions.

**Movements.** Movements that occur in joints are flexion, extension, adduction, abduction, and circumduction. Abduction and adduction are performed by the interossei, but these movements are exceedingly limited when the fingers are fully flexed.

### INTERPHALANGEAL JOINTS

The interphalangeal articulations are purely hinge joints (Figs. 5-51; 5-52), and the arrangement of their ligaments is similar to that seen in the metacarpophalangeal articulations. Each joint is surrounded by a thin fibrous articular capsule, which is reinforced on its palmar surface by thick palmar

ligaments over which glide the flexor tendons. The dorsal aspect of the capsule is largely formed by the expanded hoods of the extensor tendon, which effectively replaces the dorsal ligament. On each side the joint is fixed by obliquely oriented collateral ligaments. There are two interphalangeal joints in each of the four lateral fingers and one in the thumb.

**Movements.** The only movements permitted in the interphalangeal joints are flexion and extension. These movements are more extensive between the proximal and middle phalanges than between the middle and distal. The degree of flexion is considerable, but extension is limited by ligamentous action of the flexor tendons and by the palmar and collateral ligaments.

**Muscles Acting on the Metacarpophalangeal and Interphalangeal Joints.** Flexion of the metacarpophalangeal joints of the four medial fingers is effected by the flexors digitorum superficialis and profundus, the lumbricals, and the interossei, assisted in the case of the little finger by the flexor digiti minimi. Extension of the metacarpophalangeal joint is produced by the extensor digitorum in all

**Fig. 5-52.** Metacarpophalangeal and interphalangeal joints of a finger viewed from the ulnar or medial aspect.

four medial fingers, assisted by the extensor indicis in the index finger and the extensor digiti minimi in the little finger.

**Flexion** of the *interphalangeal joints* of the fingers is accomplished by the flexor digitorum profundus acting on both the proximal and distal joints and by the flexor digitorum superficialis acting on the proximal joints. **Extension** of the interphalangeal joint is now believed to be the result of action by not only the lumbricals and interossei, which are intrinsic hand muscles, but the long extensor digitorum muscle as well.

**Flexion** of the *metacarpophalangeal joint of the thumb* is effected by the flexors pollicis longus and brevis, and **extension** is produced by the extensor pollicis longus and brevis.

**Flexion** of the *interphalangeal joint of the thumb* is accomplished by the flexor pollicis longus, and extension is produced by the extensor pollicis longus.

## Articulations of the Lower Limb

The articulations of the lower limb include those forming the **pelvic girdle** and those of the free limb. The pelvis, which consists of the two hip bones interconnected at the **pubic symphysis**, is firmly attached to the axial skeleton by way of the **sacroiliac joints**. These structures, along with the connections of the sacrum, below to the coccyx (**sacrococcygeal joint**) and above to the fifth lumbar vertebra (**lumbosacral joint**), form the pelvic girdle. Because of these strong connections to the trunk by way of the vertebral column, the joints of the pelvic girdle were described along with those of the axial skeleton. What follows are descriptions of the remaining joints of the lower extremity.

The femur, which is the longest and largest bone in the body, articulates above with the pelvic girdle at the acetabulum to form the **hip joint**. Inferiorly, the femur joins the tibia and patella at the **knee joint**, which is the largest and most complicated of all the joints. Below the knee, the tibia and fibula are interconnected by **tibiofibular joints** in a manner somewhat similar to the bones in the forearm. At the **ankle or talocrural joint**, the tibia and fibula join the talus. In the foot, joints are located between the tarsal bones—**intertarsal joints**, and between the tarsal and metatarsal bones—**tarsometatarsal joints**. The metatarsal bones, in addition to articulating with the tarsus, interconnect with each other at the **intermetatarsal joints** and with the proximal phalanges of the

toes—**metatarsophalangeal joints**. As in the hand, each toe consists of phalanges between which are located the **interphalangeal joints**.

## HIP JOINT

This articulation is a ball-and-socket, or spheroid, joint formed by the reception of the head of the femur into the cup-shaped cavity of the acetabulum. Unlike the shoulder joints which depend on their strength from surrounding muscles, the hip joints are inherently strong, and their structure is well adapted to supporting the weight of the trunk as well as permitting a significant degree of mobility. The head of the femur forms more than half a sphere, and its articular cartilage, thicker at the center than at the circumference, covers its entire surface, except the shallow fovea of the femoral head, to which the ligament of the head of the femur is attached. The inner surface of the acetabulum is characterized by a horse-shoe-shaped region, the **lunate surface**, which also is covered by articular cartilage. Within the lunate surface is a circular depression devoid of cartilage and occupied by fatty tissue covered by synovial membrane. To the rim of the acetabulum is attached a fibrocartilaginous lip, the acetabular labrum, which significantly deepens the socket, and the joint is encased in an articular capsule which is reinforced by ligaments.

**Ligaments.** The ligamentous structures of the hip joint are:

- Articular capsule
- Iliofemoral
- Pubofemoral
- Ischiofemoral
- Ligament of the head of the femur
- Acetabular labrum
- Transverse acetabular

The **articular capsule** (Figs. 5-53; 5-54; 5-56) is strong and dense. It attaches to the pelvis **above**. **Posteriorly**, its pelvic attachment extends to the margin of the acetabulum 5 to 6 mm beyond the acetabular labrum. **Anteriorly**, it is attached to the outer margin of the labrum and, opposite the acetabular notch where the margin of the cavity is deficient, it is connected to the transverse acetabular ligament and to the edge of the obturator foramen. **Below**, the capsule surrounds the neck of the femur. This femoral attach-

FIG. 5-53. Right hip joint from the front.

ment, anteriorly, is to the intertrochanteric line; superiorly, to the base of the neck; posteriorly, to the neck, about 1.25 cm above the intertrochanteric crest; and inferiorly, to the lower part of the neck, close to the lesser trochanter. From its anterior femoral attachment along the intertrochanteric line, some of the capsular fibers are reflected proximally along the neck as longitudinal bands, termed **retinacula**. The capsule is much thicker at the upper and anterior part of the joint, where the greatest amount of resistance is required. Posteriorly and below, it is thin and more loosely attached. Blood vessels that supply the trochanters, neck, and head of the femur penetrate through the capsular attachments on the femur to achieve its upper extremity. The capsule consists of two sets of fibers, circular and longitudinal. The circular fibers, **zona orbicularis**, are deeper and more abundant at the distal and posterior part of the capsule, and form a sling or collar around the neck of the femur (Figs. 5-56; 5-57). Most of the capsular fibers are oriented longitudinally between the pelvis and the femur. They are greatest in number at the proximal and anterior part of the cap-

sule, where they are reinforced by an exceedingly strong ligamentous band, the **iliofemoral ligament**. The articular capsule is also strengthened by the pubofemoral and the **ischiofemoral ligaments**. The external surface of the capsule is rough, covered by numerous muscles, and separated anteriorly from the psoas major and iliacus by a bursa, which at times communicates by means of a circular aperture with the joint cavity.

The **iliofemoral ligament** (Fig. 5-53) is a triangular band of great strength which lies anterior to the joint and is blended intimately with the capsule. Its apex is attached superiorly to the lower part of the anterior inferior iliac spine, and to the body of the ilium between this spine and the acetabular rim. Distally, it divides into two bands, the more medial one of which passes downward to be fixed to the lower part of the intertrochanteric line. The other band is directed downward and laterally and is attached to the proximal part of the same line. Between the two bands the capsule is thinner. In some instances there is no division, and the ligament stretches to become a flat triangular band, which is attached to the whole length

FIG. 5-54. The right hip joint. Posterior aspect.

of the intertrochanteric line. This ligament is frequently called the Y-shaped ligament because it resembles an inverted Y, and its lateral band is sometimes named the **ilio-trochanteric ligament**. The iliofemoral ligament strongly limits extension at the hip joint and resists the strain put upon the anterior part of the fibrous capsule in the usual standing position, when the body weight tends to roll the pelvis backward upon the two femoral heads.

The **pubofemoral ligament** (Fig. 5-53) arises above from the body of the pubis near the acetabulum and from the adjacent superior pubic ramus. Below it passes anterior to the head of the femur to reach the femoral

neck. It blends with the capsule and with the deep surface of the more medial band of the iliofemoral ligament. The pubofemoral ligament, similar to the iliofemoral, assists in prevention of hyperextension, as well as checking excessive abduction of the thigh.

The **ischiofemoral ligament** (Fig. 5-54) consists of a triangular band of fibers that springs from the body of the ischium below and behind the acetabulum to blend with the circular fibers of the capsule. Its upper fibers are oriented horizontally across the joint, while its lower fibers spiral upward and laterally, attaching to the femoral neck just medial to the greater trochanter. Superiorly its fibers blend with the iliofemoral liga-

ment. As is the case with the other capsular ligaments, the ischiofemoral ligament becomes tense during extension of the femur.

The **ligament of the head of the femur** (Figs. 5-55; 5-56) is a triangular, somewhat flattened band implanted by its apex into the fovea or pit on the head of the femur. Its base is attached by two bands, one on each end of the acetabular notch. Between these attachments at the notch spans the transverse acetabular ligament. The ligament of the head of the femur is ensheathed by the synovial membrane, and varies greatly in strength in different subjects. Occasionally only the synovial fold exists, and in rare cases even this is absent. The ligament is made tense when the thigh is semiflexed and then adducted, and becomes relaxed when the limb is abducted. It is often too weak to

act appreciably as a ligament, but it generally contains a small artery that may assist in supplying the head of the femur in adults.

The **acetabular labrum** (Fig. 5-56) is a fibrocartilaginous rim attached to the margin of the acetabulum, thereby deepening its cavity. It protects the bony rim of the cup and smooths its surface. The labrum bridges the acetabular notch as the **transverse acetabular ligament**, thereby forming a complete circle, which closely surrounds the head of the femur and assists in holding it in place. On cross-section it is triangular in shape, and its base is attached to the margin of the acetabulum, while its opposite edge is free and sharp. Its surfaces are invested by synovial membrane. Externally it is in contact with the capsule, while internally it is inclined inwardly, narrowing the acetabu-

**Fig. 5-55.** The left hip joint which has been opened from within the pelvis. The articular surface of the head of the femur has been exposed by the removal of the floor of the acetabulum.

FIG. 5-56. A section through the hip joint.

lum and embracing the cartilaginous surface of the head of the femur.

The **transverse acetabular ligament** (Figs. 5-55; 5-56) is in reality a portion of the acetabular labrum, though differing from it in having no cartilage cells among its fibers. It arises from the margin of the acetabulum on each side of the acetabular notch and consists of strong, flattened fibers which cross the notch and convert it into a foramen through which the nutrient vessels enter the joint. The two bands of the ligament of the head of the femur are attached to the transverse acetabular ligament, one to each end.

**Synovial Membrane** (Fig. 5-57). The synovial surface is extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers the portion of the neck that is contained within the joint capsule. From the neck it is reflected as the internal surface of the capsule to cover both surfaces of the labrum and the mass of fat in the depression of the acetabular fossa. It ensheathes the ligament of the head of the femur. The joint cavity sometimes communicates with the subtendinous iliac bursa lying deep to the tendon of the psoas

major. When this occurs, the communication is found anteriorly between the pubofemoral ligament and the more medially oriented band of the iliofemoral ligament.

**Relationships of the Hip Joint** (Fig. 5-58). The hip joint is related to the muscles and tendons that surround it as well as to the vessels and nerves that pass from the pelvis into the lower extremity. **Anteriorly**, in direct contact with the joint capsule are bursae, which underlie the iliacus and the tendon of the psoas major. Anteromedially, a few of the more lateral fibers of the pectineus muscle are in contact with the capsule. More superficially are located the femoral vessels and nerves as well as the rectus femoris, sartorius, and tensor fasciae latae muscles. **Superiorly**, the reflected head of the rectus femoris muscle is adjacent to the more medial aspect of the capsule, while the gluteus minimus is closely adherent to its lateral part. **Inferiorly**, the obturator externus, the lateral fibers of the pectineus, and the medial femoral circumflex artery are in close relationship to the joint. **Posteriorly**, and closely related to the articular capsule, are the obturator externus and internus, the gemelli, and the piriformis muscles, while more superficially are found the quadratus femoris and gluteus maximus muscles, as well as the sciatic and posterior femoral cutaneous nerves. Covering all of these is the gluteus maximus.

FIG. 5-57. Synovial membrane of capsule of hip joint (distended). Posterior aspect.

**Arteries and Nerves.** The arteries to the hip joint are derived from (1) the medial femoral circumflex branch of the profunda femoral artery; (2) the obturator artery by way of the acetabular branch, which sends a small vessel along the ligament of the head of the femur; (3) the superior and inferior gluteal vessels. At times the lateral femoral circumflex artery contributes directly to the joint as well.

In the adult, vessels are seen to ascend to the femoral head from the neck of the femur in the reflected retinacular fibers of the joint capsule, anastomosing with each other and with twigs derived from the artery of the ligament of the femoral head. This latter vessel is of great importance until puberty, but as age advances and anastomotic channels develop among the other vessels, the artery accompanying the ligament of the head of the femur becomes smaller and less significant to the vascular integrity of the hip joint.

The nerves to the hip joint come from the femoral, obturator, and accessory obturator (when present) nerves to the quadratus femoris and superior gluteal.

**Movements.** The movements at the hip joint are extensive and consist of flexion, extension, adduction, abduction, circumduction, and rotation. Not only does the thigh move on the hip bone (as in walking), but also of importance are those move-

ments of the pelvis on the thigh, such as elevating the trunk from the supine position.

Although the hip joint is a freely movable ball-and-socket joint, it is essential to observe that the femur does not rotate around the long axis of the shaft because this would necessitate dislocating the femoral head from its socket. Rotation of the thigh, therefore, takes place around an imaginary axis, that is, a line drawn from the point of attachment of the ligament of the femoral head above, to the medial condyle of the femur at the knee below. Further explanations of this peculiarity rest with the fact that the neck of the femur is a segment of bone of appreciable length and that it joins the shaft at an abrupt angle (the *angle of inclination*, which averages about  $125^\circ$  in adults). All movements of the thigh must be translated into movements of the femoral neck rather than the shaft. For example, **flexion** and **extension** of the thigh as a whole are caused by rotation of the head and neck of the femur around a nearly *transverse axis*. **Rotation** of the femur occurs about a *vertical axis* which extends along a line from the head of the femur through the center of the medial condyle. During rotation of the thigh, the femoral neck swings backward and forward, while the femoral head rotates in the acetabulum around the vertical axis.

**Abduction** and **adduction** of the thigh move *both*

FIG. 5-58. Structures surrounding right hip joint.

the femoral head and neck around an *anteroposterior* axis. Abduction is somewhat freer than adduction.

The hip joint presents a striking contrast to the shoulder joint in that its mechanical arrangements ensure security and a limitation of movements. In the shoulder, the head of the humerus far exceeds the size of the articular surface of the glenoid cavity, and the ordinary movements of the humeral head are hardly restrained by the loose joint capsule. In the hip joint, on the contrary, the head of the femur is closely fitted to the acetabulum for an area extending over nearly half a sphere. At the margin of the bony cup the femoral head is still more closely embraced by the glenoid labrum, so that it is held in place by that ligament even when the fibers of the capsule have been divided. The iliofemoral ligament is the strongest of all the ligaments in the body, and it becomes stretched by any attempt to extend the femur beyond a straight line with the trunk. This ligament is the chief structure that maintains an erect position without muscular fatigue. A vertical line that descends through the center of gravity of the trunk falls behind the centers of rotation in the hip joints. The pelvis would therefore tend to fall backward, but is prevented from doing so by the tension of the iliofemoral ligaments. Even though the head of the femur and the acetabulum are di-

rectly united through the ligamentum capitis, it is doubtful whether this ligament has much influence on the security of the hip joint.

When the knee is flexed, flexion at the hip joint is arrested when the soft parts of the thigh and anterior abdominal wall are brought into contact. When the knee is extended, flexion at the hip joint is limited by the tension developed through the ligamentous action of the hamstring muscles. Extension at the hip joint is checked by the tension of the iliofemoral ligament. Adduction is limited by the thighs coming into contact, while adduction with flexion is arrested by tension developed in the lateral band of the iliofemoral ligament and the lateral part of the capsule. Although abduction is a relatively free movement, it becomes limited by the medial band of the iliofemoral ligament and the pubofemoral ligament. Lateral rotation is checked by the lateral band of the iliofemoral ligament, whereas medial rotation becomes restricted by the ischiofemoral ligament and the posterior part of the capsule.

**Muscles Producing Movements.** Flexion of the femur on the pelvis is principally produced by the psoas major, iliacus, and pectineus. Additionally, most of the other muscles that attach to the femur and the anterior aspect of the pelvis assist in flexion of the thigh. These include the rectus femoris, sartorius, tensor fasciae latae, the adductors longus and

brevis, the anterior part of the adductor magnus, the gracilis, and the anterior portions of the gluteus minimus and medius. **Extension** is mainly performed by the gluteus maximus, assisted by the hamstring muscles, including the ischial head of the adductor magnus. Accessory extensors include the gluteus medius and piriformis and even the obturator internus.

**Adduction** is produced by the adductors longus and brevis and the obturator portion of the adductor magnus, as well as the pectineus and gracilis. Accessory adductors include the gluteus maximus, obturator externus and quadratus femoris, and the hamstrings, including the ischial head of the adductor magnus and the iliopsoas. **Abduction** is chiefly performed by the gluteus medius and minimus. In addition, the tensor fasciae latae, piriformis, and sartorius also assist in abduction.

**Medial rotation** is a rather weak movement, but those muscles whose line of tension passes anterior to the vertical axis of the femoral head and neck act as medial rotators of the thigh, regardless of their insertion. These include the anterior fibers of gluteus medius and minimus, the tensor fasciae latae, the adductors longus, brevis, and magnus, the pectineus, and the iliacus and psoas major. **Lateral rotation** is a powerful movement, and results from the actions of muscles that pass across the hip joint behind the vertical axis around which the femoral head and neck rotate. The external rotators include the posterior fibers of gluteus medius and minimus, the piriformis, obturators externus and internus, gemellus superior, gemellus inferior, quadratus femoris, gluteus maximus, and sartorius.

## KNEE JOINT

The knee joint is the largest joint in the body. Although structurally it resembles a hinge joint, its movements are more complicated than those at a simple hinge joint, because rotation and gliding movements also occur at the knee. The knee joint is vulnerable because of the incongruence of the apposing articular surfaces (Figs. 5-59; 5-60), but its great stability is maintained by the arrangement and strength of its ligaments and the muscles and tendons that pass across the joint. The knee joint is a compound joint, and might conveniently be regarded as consisting of three articulations with a common joint cavity. There are two condyloid joints, one between each condyle of the femur and the corresponding condyle of the tibia, and a third between the patella and the femur, classified as a saddle or sellar type of joint (Fig. 5-60). Each of the condyloid joints is partially divided by a fibrocar-

**Fig. 5-59.** Anteroposterior roentgenogram of the adult knee. 1, Medial condyle of femur. 2, Medial condyle of tibia. 3, Lateral condyle of femur. 4, Lateral condyle of tibia. 5, Medial intercondylar tubercle of tibia. 6, Lateral intercondylar tubercle of tibia. 7, Adductor tubercle of femur. 8, Head of fibula. The gap between the lateral condyles of the femur and tibia is occupied by the articular cartilage of the two bones and by the lateral meniscus.

tilaginous meniscus interposed between the corresponding articular condyles. Some phylogenetic evidence supports this concept of knee joint structure. In some lower mammals the knee joint consists of three separate synovial cavities that are either entirely distinct or connected by only small communicating channels and correspond to the three articulations in the human knee cavity. This view is strengthened by the existence of two cruciate ligaments in the middle of the knee joint that can be regarded as collateral ligaments of the medial and lateral condylar joints.

**Articular Surfaces.** The tibial condyles present two cartilage-covered articular surfaces, which are nearly flat but slightly concave, and which are separated by the intercondylar area (Fig. 5-59). Although the facet of the medial condyle lies entirely upon the superior surface of the tibia, the facet of the

**Fig. 5-60.** Lateral roentgenogram of the partially flexed adult knee. 1, Patella. 2, Margin of the lateral condyle of the tibia. 3, Margin of the medial condyle of the tibia. 4, Intercondylar eminences of the tibia. 5, Apex of the head of the fibula. 6, Tibiofibular articulation (proximal). Observe that the medial condyle of the femur descends slightly lower than the lateral condyle and that the superior surface of the tibia and the femoral condyles present incongruous bony contours.

lateral condyle is extended somewhat over the posterior condylar margin where the tendon of the popliteus muscle attaches to the lateral meniscus. The two **femoral condyles** are rounded (Fig. 5-60) and they are curved more posteriorly than anteriorly. They are convex both anteroposteriorly and from side to side, and the condyles are separated posteriorly by the deep intercondylar notch. Anteriorly the condyles fuse to form the patellar surface of the femur. The two femoral condyles are of different shapes. The distal surface of the medial condyle is narrower and longer than that of the lateral condyle.

Attached principally to the periphery of the tibial condyles are the fibrocartilaginous **menisci**, which only slightly deepen the concavities on the superior surface of the tibia. The menisci are importantly involved in the rotation of the femur at the knee. The femur and tibia are not in direct alignment vertically, because the femur slants slightly inward at the knee, whereas the tibia is nearly vertical.

The articular surface of the patella fits rather imperfectly within the concavity of the patellar surface of the femur (Fig. 5-60). A longitudinal ridge divides the articular surface of the patella into a large lateral and a smaller medial part. The latter is further subdivided by another vertical ridge into two smaller areas.

**Ligaments.** The ligaments interconnecting the bones at the knee are:

- Articular capsule
- Patellar
- Oblique popliteal
- Arcuate popliteal
- Tibial collateral
- Fibular collateral
- Anterior cruciate
- Posterior cruciate
- Medial meniscus
- Lateral meniscus
- Transverse

The **articular capsule** (Figs. 5-61; 5-62) is a complex structure which does not form a

Fig. 5-61. Right knee joint. Anterior view.

complete fibrous sac as is generally found in other joints. Instead, throughout most of its extent the fibrous capsule consists of muscle tendons or tendinous expansions between which a few true capsular fibers are found interconnecting the articulating bones. Its inner surface is lined by a synovial membrane, but often this synovial lining is separated from the fibrous-ligamentous layer by various other structures within the joint such as fat pads and the menisci. Anteriorly, the fibrous layer of the capsule is completely lacking above the patella, and deep to the tendon of the quadriceps femoris is directly found the synovial lining. At the level of the patella and inferior to the patella, the anteromedial and anterolateral aspects of the fibrous capsule blend with expansions of the tendons of the vastus medialis and vastus lateralis muscles, as well as the fascia lata and its iliotibial band (Fig. 5-61). These fill the intervals between the patellar ligament and collateral ligaments and constitute the **medial and lateral patellar retinacula**, which descend to attach to the anterior rim of the

tibial condyles. **Posteriorly**, the capsule consists of vertical fibers which arise above from the margins of the femoral condyles and from the borders of the intercondylar fossa of the femur. The capsule descends to attach to the posterior margins of the tibial condyles. The lines of attachment of the posterior part of the articular capsule are situated on the sides of and anterior to the cruciate ligaments; these are, therefore, excluded from the joint cavity. Blending with the capsular fibers, posteriorly and above, are the tendons of origin of the two heads of the gastrocnemius muscle. A bit lower stretches the oblique popliteal ligament, which strengthens the capsule as it expands upward and laterally from the insertion of the tendon of the semimembranosus (Fig. 5-62). **Laterally**, capsular fibers stretch from the border of the lateral femoral condyle above the origin of the popliteus muscle to the lateral aspect of the tibial condyle and the head of the fibula. The fibular collateral ligament remains distinct from the capsule. **Medially**, the articular capsule attaches above to the margin of the medial femoral condyle and below to the corresponding margin of the medial tibial

Fig. 5-62. The right knee joint. Posterior aspect.

condyle. Fibrous expansions from the sartorius and semimembranosus pass proximally to the tibial collateral ligament, strengthening the capsule. On the deep side of the capsule medially is a thickening that extends from the medial epicondyle of the femur to the medial meniscus (Last, 1948). Considered today as a deep portion of the tibial collateral ligament, it holds the medial convexity of the meniscus firmly to the femur.

The **patellar ligament** (Fig. 5-61) is the central portion of the common tendon of the quadriceps femoris, which is continued from the patella to the tuberosity of the tibia. It is an extremely strong, flat band, about 8 cm in length, attached above to the apex and adjoining margins of the patella and the rough depression on its posterior surface, and below to the tuberosity of the tibia. Its superficial fibers are continuous over the front of the patella with those of the tendon of the quadriceps femoris. The medial and lateral portions of the tendon of the quadriceps pass down on each side of the patella, to be inserted into the proximal extremity of the tibia along the sides of its tuberosity. These portions merge into the capsule, to form the **medial and lateral patellar retinacula**. The posterior surface of the patellar ligament is separated from the synovial membrane of the joint by a large infrapatellar pad of fat, and from the tibia by a bursa.

The **oblique popliteal ligament** (Fig. 5-62) is a broad, flat fibrous band of great strength which blends into and reinforces the posterior part of the joint capsule. Its obliquely coursing fibers are attached laterally and proximally to the margin of the intercondylar fossa and posterior surface of the lateral condyle of the femur, and distally to the posterior margin of the medial condyle of the tibia. Many of its more superficial fibers are derived from the tendon of the semimembranosus muscle, passing upward and laterally from the insertion site of that muscle. The oblique popliteal ligament is perforated by branches of the middle genicular vessels as well as articular nerve filaments. It forms part of the floor of the popliteal fossa, and the popliteal artery rests upon it.

The **arcuate popliteal ligament** (Fig. 5-62) is a triangular band of capsular fibers attached above to the posterior aspect of the lateral condyle of the femur. It arches medially and downward in the posterior part of the knee joint capsule, over the tendon of the

popliteus muscle, to attach to the posterior border of the intercondylar area of the tibia and to the posterior surface of the apex of the fibular head.

The **tibial collateral ligament** (Figs. 5-61 to 5-63; 5-66) is a broad, flat band situated on the medial aspect of the knee joint, nearer the posterior part of the joint than the anterior. It is attached above to the medial epicondyle of the femur immediately below the adductor tubercle, and below, to the medial condyle and medial surface of the shaft of the tibia. The fibers of the posterior part of the ligament are short and are inserted into the medial condyle of the tibia proximal to the groove for the semimembranosus. The anterior part of the ligament is a flattened band, about 10 cm long, which inclines forward as it descends to be inserted into the medial surface of the shaft of the tibia about 2.5 cm distal to the level of the condyle. It is crossed, at its distal part, by the tendons of the sartorius, gracilis, and semitendinosus, a bursa being interposed. Inferiorly, its deep surface covers the inferior medial genicular vessels and nerve and the anterior portion of the tendon of the semimembranosus, to which it is connected by a few fibers.

**Fig. 5-63.** The right knee joint. Flexed and dissected anteriorly.

The anterior margin of the ligament is free, but its posterior margin is firmly attached to the medial meniscus as it descends past the mid-region of the joint.

The **fibular collateral ligament** (Figs. 5-62; 5-63; 5-66) is a strong, rounded fibrous cord, attached *above* to the posterior part of the lateral epicondyle of the femur, immediately above the groove for the tendon of the popliteus muscle, and *below* to the lateral side of the head of the fibula anterior to its apex. The greater part of its lateral surface is covered by the tendon of the biceps femoris, although the tendon divides at its insertion into two parts which are separated by the ligament. Deep to the ligament are the tendon of the popliteus muscle (Fig. 5-64) and the inferior lateral genicular vessels and nerve. The ligament lies free from the capsule and has no attachment to the lateral meniscus.

The **cruciate ligaments** (Figs. 5-63 to 5-68) are two intra-articular ligaments of considerable strength, situated in the middle of the joint, nearer its posterior than its anterior surface. They are called **cruciate** because they cross each other somewhat like the lines of the letter X, and have received the names **anterior** and **posterior**, from the position of their attachments to the tibia.

The **anterior cruciate ligament** (Figs. 5-63 to 5-65) is attached to a depression in the anterior intercondylar area on the surface of the tibial plateau. This tibial attachment lies in front of the anterior intercondylar tubercle and is blended with the anterior extremity of the lateral meniscus. It passes upward, backward, and laterally, to be fixed into the posterior part of the medial surface of the lateral condyle of the femur (Figs. 5-64; 5-65).

The anterior cruciate ligament limits hyperextension of the knee as well as prevents the backward sliding of the femur on the tibial plateau. Its limitation of extension of the lateral condyle, to which it is attached, then causes medial rotation of the femur as the unencumbered medial condyle continues to extend, until it achieves its full extension. The collateral ligaments of the knee along with the oblique popliteal ligament then become taut, thereby limiting further rotation as the knee joint becomes locked. This "screw home" action, to which the anterior cruciate ligament importantly contributes, allows the knee to attain rigidity.

In contrast, when the foot is solidly on the ground, thereby fixing the leg, the anterior cruciate ligament assists in limiting medial rotation.

**Fig. 5-64.** The anterior cruciate ligament during **extension** in the right knee joint. Medial view. The lower medial half of the femur, including the medial femoral condyle, has been removed to expose fully the ligament. 1, Anterior cruciate ligament. 2, Lateral femoral condyle. 3, Medial meniscus. 4, Lateral meniscus. (From Girgis, Marshall and Al-Monajem, 1975.)

The **posterior cruciate ligament** (Figs. 5-66 to 5-68) is stronger, but shorter and less oblique in its direction than the anterior. It is attached to a depression on the posterior intercondylar area of the tibia, and extends slightly onto the contiguous posterior surface of the tibia. It also is attached to the posterior extremity of the lateral meniscus.

Passing upward, forward, and medially, the posterior cruciate ligament is fixed to the lateral surface of the medial femoral condyle (Figs. 5-67; 5-68).

The posterior cruciate ligament prevents hyperflexion of the knee, and its attachments prevent the femur from sliding forward on the superior tibial surface when the knee is flexed. This function of the ligament is especially important in walking down a

**FIG. 5-65.** The anterior cruciate ligament during flexion in the right knee joint. Medial view. As in Figure 5-64, the medial femoral condyle has been removed. Note the tightness of the anteromedial band of the anterior cruciate ligament (arrow) during flexion and the looseness of the major part of the ligament. 1, Anterior cruciate ligament. 2, Lateral femoral condyle. 3, Medial meniscus. 4, Lateral meniscus. (From Girgis, Marshall and Al-Monajem, 1975.)

steep incline or down steps, when the body weight is transferred to the tibia at the same time as the knee joint flexes.

The **menisci** (Fig. 5-69) are two crescentic lamellae that serve to deepen the surfaces of the articular plateau on the head of the tibia for reception of the condyles of the femur. The peripheral outer border of each meniscus is thick and convex, while the opposite inner border tapers to a thin free edge. The upper surfaces of the menisci are concave, and in contact with the condyles of the femur, and their lower surfaces are flat, and rest upon the head of the tibia. Both surfaces are smooth, and adjacent to synovial membrane. Each meniscus covers approximately the peripheral two-thirds of the corresponding articular surface of the tibia. The peripheral rim of each meniscus is connected to the margin of the tibial head by portions of the fibrous capsule that are called the **coronary ligaments**.

The **medial meniscus** (Figs. 5-63; 5-66; 5-69; 5-70) is nearly semicircular in form, and broader posteriorly than in front. Its anterior end, thin and pointed, is attached to the anterior intercondylar area of the tibia, in front of the anterior cruciate ligament (Fig. 5-63).

**FIG. 5-66.** Left knee joint, posterior aspect, showing interior ligaments.

**FIG. 5-67.** The posterior cruciate ligament during **extension** of the right knee joint. Posterolateral view. The lower lateral part of the femur, including the lateral condyle, has been removed to reveal the attachments of the ligament. Only the posterior band of the ligament (arrow) becomes taut during extension. 1, Posterior cruciate ligament. 2, Medial femoral condyle. 3, Lateral meniscus. 4, Medial meniscus. (From Girgis, Marshall and Al-Monajem, 1975.)

and a band of fibers behind the tibial attachment is continuous with the transverse ligament of the knee (Figs. 5-66; 5-69). Its posterior end is fixed to the posterior intercondylar area of the tibia, between the attachments of the lateral meniscus and the posterior cruciate ligament. The circumference of the medial meniscus is attached to the joint capsule and to the deep surface of the tibial collateral ligament.

The **lateral meniscus** (Figs. 5-63; 5-66; 5-69) is nearly circular in form. It covers a larger portion of the tibial articular surface, but is less firmly attached than the medial. The meniscus is grooved laterally for the tendon of the popliteus muscle, which separates it from the fibular collateral ligament. Its ante-

rior end is attached in front of the intercondylar eminence of the tibia, lateral to and behind the anterior cruciate ligament with which it blends. Additionally, the anterior convex margin of the lateral meniscus attaches to the transverse ligament of the knee (Fig. 5-69). The posterior end is attached behind the intercondylar eminence of the tibia and in front of the posterior end of the medial meniscus. The anterior attachment of the lateral meniscus is twisted on itself and rests on a sloping shelf of bone on the lateral process of the intercondylar eminence. Close to its posterior attachment it sends off a strong fasciculus, the **posterior meniscofemoral ligament** (of Wrisberg), which passes upward and medially to be inserted into the medial condyle of the femur, immediately behind the attachment of the posterior cruciate ligament (Figs. 5-66; 5-69). Occasionally, another small fasciculus, the **anterior meniscofemoral ligament** (of Humphrey), also attaches to the posterior part of the lateral meniscus, and passes in front of the posterior cruciate ligament to be inserted into the medial condyle of the femur. One or the other of the meniscofemoral ligaments are found in about 70% of

**FIG. 5-68.** The posterior cruciate ligament during **flexion** of the right knee joint. Posterolateral view. As in Figure 5-66, the lateral femoral condyle has been removed. During flexion the small posterior band of the ligament (arrow) is loose while the remaining major portion of the ligament is taut. 1, Posterior cruciate ligament. 2, Medial condyle. 3, Lateral meniscus. 4, Medial meniscus. (From Girgis, Marshall and Al-Monajem, 1975.)

**FIG. 5-69.** Head of right tibia seen from above, showing the menisci and the attachments onto the tibia of the cruciate ligaments.

**FIG. 5-70.** Sagittal section of right knee joint, showing the infrapatellar fat pad and certain bursae.

knee joints (Girgis, Marshall, and Al-Monajem, 1975).

The **transverse ligament** of the knee (Fig. 5-69) connects the anterior convex margin of the lateral meniscus to the anterior end of the medial meniscus. Its thickness varies considerably in different subjects, and it is sometimes absent.

**Synovial Membrane.** The synovial membrane of the knee joint is the most extensive and complicated joint in the body. Originating at the proximal border of the patella, it forms a large sac beneath the quadriceps femoris (Fig. 5-71) on the distal part of the front of the femur. Although frequently referred to as the **suprapatellar bursa**, it is not a true frictional bursa, but only an extension of the synovial cavity above the patella. This large pouch of synovial membrane is supported during movements of the knee by a small muscle, the articularis genu, which inserts into it. On both sides of the patella, the synovial membrane extends beneath the aponeuroses of the vasti muscles, but more especially beneath that of the vastus medialis. Distal to the patella it is sepa-

rated from the patellar ligament by a considerable quantity of fat, known as the **infrapatellar fat pad**. From both the medial and lateral borders of the articular surface of the patella, the synovial membrane projects as two fringe-like folds to the interior of the joint. These are called the **alar folds**, which converge and continue as a single band, the **infrapatellar synovial fold**, to attach to the anterior aspect of the intercondylar fossa of the femur. At the upper posterior aspect of the joint, the synovial membrane forms two pouches that lie deep to the origins of the gastrocnemius muscles (Fig. 5-72).

On both sides of the joint, the synovial membrane passes downward from the femur, lining the capsule to its point of attachment to the menisci. It may then be traced over the proximal surfaces of the menisci to their free borders, which are not covered by synovial membrane, and then along their distal surfaces to the tibia (Figs. 5-71; 5-72). At the posterior part of the lateral meniscus, the synovial membrane forms a small sac, the **subpopliteal recess**, between the groove on the surface of the meniscus and the tendon of the popliteus muscle. The membrane is reflected anteriorly across the cruciate ligaments, which are therefore excluded from the synovial cavity.

**FIG. 5-71.** Synovial membrane of the articular capsule of right knee joint (distended and colored blue). Lateral aspect.

**Fig. 5-72.** Synovial membrane of the articular capsule of right knee joint (distended and colored blue). Posterior aspect.

**Bursae** (Figs. 5-70 to 5-72). The bursae related to the knee joint are the following.

**Anteriorly** there are *four* bursae: (1) the large **subcutaneous prepatellar bursa**, interposed between the patella and the skin; (2) the smaller **deep infrapatellar bursa** between the upper part of the tibia and the patellar ligament; (3) the **subcutaneous infrapatellar bursa** between the lower part of the tuberosity of the tibia and the skin; (4) the **suprapatellar bursa** between the anterior surface of the lower part of the femur and the deep surface of the quadriceps femoris, which usually communicates with the knee joint.

**Laterally** there are *four* bursae: (1) the **lateral gastrocnemius bursa**, which sometimes communicates with the joint, between the lateral head of the gastrocnemius muscle and the capsule; (2) the **inferior biceps femoris bursa** between the fibular collateral ligament and the tendon of the biceps femoris muscle; (3) one between the fibular collateral ligament and the tendon of the popliteus muscle (this is sometimes only an expansion from the next bursa); (4) the **popliteus bursa** between the tendon of the popliteus and the lateral condyle of the femur, which is usually an extension from the synovial membrane of the joint.

**Medially**, there are *five* bursae: (1) the **medial**

**gastrocnemius bursa** between the medial head of the gastrocnemius and the capsule; this sends a prolongation between the tendon of the medial head of the gastrocnemius and the tendon of the semimembranosus and often communicates with the joint; (2) the **anserine bursa**, superficial to the tibial collateral ligament, and between it and the tendons of the sartorius, gracilis, and semitendinosus; (3) one deep to the tibial collateral ligament, and between it and the tendon of the semimembranosus (this is sometimes only an expansion from the next bursa); (4) one between the tendon of the semimembranosus and the medial condyle of the tibia; (5) occasionally there is a bursa between the tendons of the semimembranosus and semitendinosus muscles.

**Structures Around the Joint.** **Anteriorly**, the knee joint is covered by the tendon of the quadriceps femoris. Expanding anteromedially and anterolaterally are the tendons of the vastus medialis and vastus lateralis, forming the medial and lateral patellar retinacula. **Laterally** in relationship to the joint are the tendons of the biceps femoris and popliteus muscles and the common peroneal nerve. **Medially** are found the sartorius, gracilis, semitendinosus, and semimembranosus muscles. **Posteriorly** and within the popliteal fossa are located the popliteal artery and vein, and the tibial nerve along with

lymph nodes and fat. Also found posteriorly are the popliteus and plantaris muscles and the medial and lateral heads of the gastrocnemius muscle.

**Arteries and Nerves.** The arteries supplying the knee joint form an anastomosis that includes the descending genicular branch of the femoral artery, the genicular branches of the popliteal, the recurrent branches of the anterior tibial, and the descending branch from the lateral femoral circumflex branch of the deep (profunda) femoral artery.

The nerves that supply the knee joint are sensory articular branches from the obturator, femoral, common peroneal, and tibial nerves.

**Movements.** The movements that take place at the knee joint are flexion and extension, and medial and lateral rotation.

The movements of flexion and extension at the knee differ from those in a typical hinge joint, such as the elbow, because (1) the femoral condyles are curved in such a way that the axis around which flexion and extension occur is not fixed, but shifts somewhat forward during extension and backward during flexion of the leg on the thigh; and (2) *with the foot firmly fixed on the ground*, the commencement of flexion (as in the assumption of a sitting position from a standing position) is accompanied by some lateral rotation of the femur, and at the end of extension (as in arising from a sitting position), a considerable medial rotation of the femur occurs. *With the foot off the ground*, extension (as in swinging of the leg in the air while sitting in a chair) is accompanied by lateral rotation of the tibia, and flexion with medial rotation of the tibia.

The movement from full flexion to full extension with the foot firmly stabilized on the ground (as in arising from a sitting position) may be described by the following phases:

1. In the fully flexed position, the posterior parts of the femoral condyles rest on the corresponding surfaces of the tibial articular plateau, and their superimposed menisci.

2. During extension of the thigh at the knee joint from the fully flexed position, *the tibia and the menisci glide forward*, so that the axis, which at the initiation of movement is represented by a line through the medial and lateral condyles of the femur, gradually shifts anteriorly.

3. The lateral condyle of the femur is brought almost to rest by the tightening of the anterior cruciate ligament; however, it moves slightly anterior and medialward, pushing before it the anterior part of the lateral meniscus. Because the articular surface of the medial condyle is prolonged farther anteriorly than that of the lateral condyle, as the anterior movement of the condyles is checked by the anterior cruciate ligament, continued muscular action causes the medial condyle to drag with it the medial meniscus and to travel posteriorly and medially, thus producing a medial rotation of the femur on the tibia.

4. When the position of full extension is reached, medial rotation of the femur causes tautness in the

oblique popliteal ligament as well as in the two collateral ligaments, preventing further medial rotation. The knee joint, now fully extended and the femur medially rotated, is rigid and locked in the so-called "screw home" position.

5. In standing erect, the weight of the body falls in front of a line carried across the centers of the knee joints, and therefore tends to produce overextension of the articulations. This, however, is prevented by the tension of the anterior cruciate, oblique popliteal, and collateral ligaments.

The movement of flexion from the fully extended position results from the converse of the above phases. Therefore, it is preceded by a lateral rotation of the femur which unlocks the extended joint. This initial lateral rotation of the femur at the commencement of flexion is produced by the popliteus muscle (Last, 1950).

In addition to flexion and extension and the passive rotation essential for their initiation or completion (conjunct rotation), a certain degree of active voluntary rotation at the knee joint (adjunct rotation) can be achieved *when the knee is partially flexed*, because the cruciate and collateral ligaments are not fully tightened at that time. Voluntary rotation cannot be performed when the knee is in full extension.

**Movements of the Patella.** The articular surface of the patella is indistinctly divided into seven facets—proximal, middle, and distal horizontal pairs, and a medial perpendicular facet (Fig. 5-73). When the knee is forcibly flexed, the medial perpendicular facet is in contact with the crescentic semilunar area on the lateral part of the medial condyle of the femur. As the leg is carried from the flexed to the extended position, first the proximal pair, then the middle pair, and last the distal pair of horizontal facets is successively brought into contact with the patellar surface of the femur. In the fully extended position, when the quadriceps femoris is relaxed, the patella lies loosely covering the anterior aspect of the distal surface of the femur, extending slightly distal to the tibial rim.

**Role of Ligaments During Movement.** During flexion, the patellar ligament is stretched, and in extreme flexion much of the posterior cruciate and the oblique popliteal ligaments are tense, but the two collateral ligaments and the major part of the anterior cruciate ligament are relaxed. Flexion is checked by the contact of the soft structures of the calf with the thigh. In full extension of the knee joint, the oblique popliteal and collateral ligaments, the anterior cruciate ligament, and most of the posterior cruciate ligament, are rendered tense. In the act of extending the leg, the patellar ligament is tightened by the quadriceps femoris, but in full extension with the heel supported, the patellar ligament is relaxed and the patella can be easily moved.

When the leg is partially flexed, all ligaments with the exception of the anterior part of the tibial collateral ligament are somewhat more relaxed than in full extension. In this situation, up to 50° of voluntary

**Fig. 5-73.** Posterior surface of the right patella, showing its different areas of contact with the femur in varying positions of the knee joint.

rotation (adjunct rotation) of the leg at the knee can occur. Thus, **medial rotation** of the tibia tends to twist the cruciate ligaments, making them taut, and thereby checking the movement. **Lateral rotation** is checked by the collateral ligaments.

The main function of the **cruciate ligaments** is to act as a direct bond between the tibia and femur and to prevent the tibial plateau from being carried too far backward or forward during movements of the leg at the knee joint. The anterior cruciate ligament prevents forward gliding of the tibia on the femur, while the posterior cruciate ligament prevents backward gliding of the tibia. The cruciate ligaments also assist the collateral ligaments in resisting any bending of the joint to the sides. The **menisci** adapt the surface of the tibial plateau to the shape of the femoral condyles, but their role during movement at the knee joint is limited to rotation and not to flexion or extension. They also appear to spread synovial fluid, thereby assisting in lubrication of the knee joint. The **patella** affords important protection to the front of the knee joint, and distributes the pressure during kneeling which would otherwise fall upon the prominent ridges of the femoral condyles. It also affords leverage to the quadriceps femoris muscle, and strength to its tendinous attachment.

**Role of Muscles During Movement.** Muscles are an indispensable factor in maintaining the stability of the knee joint. Their role in movements at the joint will simply be summarized at this point. **Extension** of the leg on the thigh is performed principally by the quadriceps femoris. **Flexion** of the leg at the knee joint results from action of the biceps femoris, semitendinosus, and semimembranosus, assisted by the gracilis, sartorius, gastrocnemius, popliteus, and plantaris. **Lateral rotation** of the free non-weight-bearing leg is effected by the biceps femoris, and its **medial rotation** by the popliteus, semitendinosus, and, to a slight extent, the semimembranosus, the sartorius, and the gracilis.

The **popliteus muscle** comes into action at the commencement of the movement of flexion of the knee. By its contraction the leg is rotated medialward, or, if the tibia is fixed, the thigh is rotated lateralward, and the knee joint is unlocked.

**Clinical Interest.** The articular structures of the knee joint are not contoured in a manner that would lend stability to the joint. This poor adaptation of the

bony surfaces of the joint is helped considerably by the strength of the ligaments and overlying muscles which do, in fact, allow the joint considerable strength and weight-bearing durability. However, their inextensible nature and their tautness frequently result in tearing injuries of the ligaments and the menisci when excessive strains are accidentally sustained. The most common athletic injury of the knee involves a tear of the tibial collateral ligament and/or the medial meniscus, to which this ligament is securely attached. This occurs when the foot of the victim is firmly planted on the ground and the knee is semiflexed. An impact, especially from behind, could cause a shift in the weight of the body to medially rotate the femur severely. The leg, which is forced into abduction, shears the tibial collateral ligament or tears the medial meniscus, or both.

### TIBIOFIBULAR JOINTS

The tibia and fibula are connected at their proximal extremities by means of a synovial joint, and at their distal extremities by a fibrous joint. Additionally an interosseous membrane joins the shafts of the two bones.

**SUPERIOR TIBIOFIBULAR JOINT.** This articulation is a plane or gliding joint between the lateral condyle of the tibia and the head of the fibula. The contiguous surfaces of the bones present flat, oval facets covered with cartilage and connected together by an articular capsule, which is lined by a synovial membrane and strengthened by the anterior and posterior ligaments of the head of the fibula.

**Ligaments.** The **articular capsule** surrounds the joint and is attached around the margins of the articular facets on the tibia and fibula. It is much thicker anteriorly than posteriorly. The capsule is lined by a synovial membrane, the cavity of which is closed off completely from the knee joint anteriorly. In some instances the synovial cavity may communicate with that of the knee joint posterolaterally by means of the popliteal bursa deep to the tendon of the popliteus muscle.

The **anterior ligament of the head of the fibula** (Fig. 5-63) consists of two or three broad, flat bands which pass obliquely upward from the front of the head of the fibula to the anterior part of the lateral condyle of the tibia.

The **posterior ligament of the head of the fibula** (Fig. 5-66) is a single thick, broad band which passes obliquely upward from the back of the head of the fibula to the posterior

part of the lateral condyle of the tibia. It is covered by the tendon of the popliteus muscle.

**CRURAL INTEROSSEOUS MEMBRANE.** An interosseous membrane extends between the interosseous crests of the tibia and fibula, thereby separating the muscles on the anterior from those on the posterior aspect of the leg. The membrane is a thin but strong lamina composed of oblique fibers, which for the most part course downward and laterally, but a few fibers pass in the opposite direction. Proximally, its margin does not quite reach the superior tibiofibular joint, but presents a free concave border, above which is a large, oval aperture for the passage of the anterior tibial artery and vein which supply and drain the front of the leg. Distally, there is another oval opening in the membrane for passage of the perforating anterior peroneal vessels. The membrane is continuous inferiorly with the interosseous ligament of the inferior tibiofibular joint and presents numerous perforations for the passage of small vessels. It is related anteriorly to the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius muscles, and the anterior tibial vessels and deep peroneal nerve. Posteriorly, it lies adjacent to the tibialis posterior and flexor hallucis longus muscles.

**INFERIOR TIBIOFIBULAR JOINT** (Fig. 5-74). This articulation is formed by a rough, triangular, convex surface on the medial side of the distal end of the fibula, and the rough concave fibular notch on the lateral side of the distal tibia. For the most part this is a fibrous joint of the syndesmosis type with its surfaces interconnected by an interosseous ligament. The bony surfaces of the distal one-half centimeter of the joint, however, are smooth, covered with cartilage, and lined by a synovial membrane that is continuous with that of the ankle joint.

**Ligaments.** The ligaments of this joint are:

- Anterior tibiofibular
- Posterior tibiofibular
- Inferior transverse
- Interosseous

The **anterior tibiofibular ligament** (Figs. 5-74; 5-76) is a flat band of fibers, broader below than above, which extends obliquely downward and laterally between the adjacent margins of the tibia and fibula on the anterior aspect of the joint. Anterior to the

ligament is found the peroneus tertius muscle, the aponeurosis of the leg, and the integument. Posteriorly, it lies in contact with the interosseous ligament and the cartilage covering the talus.

The **posterior tibiofibular ligament** (Figs. 5-74; 5-77) is somewhat smaller than the anterior ligament, but disposed in a similar manner across the posterior surface of the joint. Inferiorly, it is continuous with the more deeply (i.e., anteriorly) placed inferior transverse ligament.

The **inferior transverse ligament** (Fig. 5-77) lies in front of and below the posterior tibiofibular ligament. It is a strong, thick band of yellowish fibers that passes transversely across the posterior aspect of the joint, from the medial surface of the lateral malleolus of the fibula to the posterior border of the articular surface of the tibia, almost as far as its malleolar process. This ligament, containing yellow elastic fibers, projects below the margin of the bones, and forms part of the articulating surface for the talus.

The **interosseous ligament** (Fig. 5-78) consists of numerous short, strong, fibrous bands which pass between the contiguous rough surfaces of the tibia and fibula, and constitute the chief bond of union between the bones. It is continuous proximally with the crural interosseous membrane.

### TALOCRURAL OR ANKLE JOINT

The ankle joint (Figs. 4-74 to 4-78) is principally uniaxial and classified as a ginglymus, or hinge joint. The structures entering into its formation above are the lower end of the tibia and its malleolus, the malleolus of the fibula, and the inferior transverse ligament, which together form a deep cavity for the reception of the proximal convex surface of the talus and its medial and lateral facets.

**Ligaments.** The bones are connected by the following ligaments:

- Articular capsule
- Deltoid
- Anterior talofibular
- Posterior talofibular
- Calcaneofibular

The **articular capsule** surrounds the joint and is attached above to the borders of the articular surfaces of the tibia and malleoli, and below to the talus around its articular

FIG. 5-74. The inferior tibiofibular joint and the lateral aspect of the ankle joint of the right lower limb.

surface. The **anterior part** of the capsule is a broad, thin, membranous layer which stretches from the anterior margin of the distal end of the tibia to the rough dorsal surface of the neck of the talus, somewhat in front of its superior articular surface. Lying in front of the anterior part of the capsule are the extensor tendons of the toes, the tendons of the tibialis anterior and peroneus tertius, and the anterior tibial vessels and deep peroneal nerve. The **posterior part** of the capsule is thin, and consists principally of transverse fibers. It is attached above to the margin of the articular surface of the tibia, blending with the transverse ligament, and extends below to the talus. It is somewhat thickened laterally, and attaches near the lateral malleolar fossa of the fibula. The inner aspect of the capsule is lined by a synovial membrane that invests the deep surfaces of the ligaments, and sends a small process proximally between the distal ends of the tibia and fibula.

The **deltoid (or medial) ligament** (Figs. 5-75; 5-77) is a strong, flat, triangular band, attached above to the apex and anterior and posterior borders of the medial malleolus. It consists of two sets of fibers, superficial and deep. Of the *superficial fibers* the most anterior (**tibionavicular part**) pass forward to be inserted into the tuberosity of the navicular

bone, and immediately behind this they blend with the medial margin of the plantar calcaneonavicular ligament. The middle fibers (**tibiocalcaneal part**) descend almost perpendicularly to be inserted into the whole length of the sustentaculum tali of the calcaneus. The posterior fibers (**posterior tibiotalar part**) pass backward and laterally to be attached to the inner side of the talus, and to the prominent tubercle on its posterior surface, medial to the groove for the tendon of the flexor hallucis longus. The *deep fibers* (**anterior tibiotalar part**) are attached above to the tip of the medial malleolus, and below to the medial surface of the talus. Crossing the surface of the deltoid ligament are the tendons of the tibialis posterior and the flexor digitorum longus muscles.

The *lateral aspect of the ankle joint* is reinforced by three quite distinct ligamentous bands, the anterior and posterior talofibular ligaments and the calcaneofibular ligament. Some descriptions consider these as three fascicles of a single **lateral ligament** of the ankle joint.

The **anterior talofibular ligament** (Figs. 5-74; 5-76), the shortest of the three, passes forward and medially from the anterior margin of the fibular malleolus to the talus, where it attaches in front of its lateral articular facet and laterally on its neck.

**FIG. 5-75.** The ligaments of the right ankle and tarsus. Medial aspect.

**FIG. 5-76.** The ligaments of the right ankle and tarsus. Lateral aspect.

The **posterior talofibular ligament** (Figs. 5-74; 5-76; 5-77) is the strongest and most deeply seated of the ligaments on the lateral aspect of the ankle joint. It courses almost horizontally from the posterior part of the lateral malleolar fossa of the fibula to a prominent tubercle on the posterior surface of the talus immediately lateral to the groove for the tendon of the flexor hallucis longus.

The **calcaneofibular ligament** (Figs. 5-74; 5-76) is the longest of the three lateral ligaments and extends as a narrow, rounded cord from the apex of the fibular malleolus, downward and slightly backward, to a tubercle on the lateral surface of the calcaneus. It is covered by the tendons of the peroneus longus and brevis muscles.

**Relations.** Located **anterior** to the ankle joint from medial to lateral are the tibialis anterior, extensor hallucis longus, anterior tibial vessels, deep peroneal nerve, extensor digitorum longus, and peroneus tertius. Over the **posterior** aspect of the joint from medial to lateral are found the tibialis posterior, flexor digitorum longus, posterior tibial vessels, tibial nerve, flexor hallucis longus, and, in the groove behind the fibular malleolus, the tendons of the peroneus longus and brevis.

**Arteries and Nerves.** The arteries supplying the joint are derived from the malleolar branches of the anterior tibial and the peroneal. The nerves come from the deep peroneal and tibial.

**Movements.** When the body is in the erect position, the foot is at a right angle to the leg. The movements of the ankle joint are those of dorsiflexion and plantar flexion.

**Dorsiflexion** results from an approximation of the foot to the front of the leg, whereas during **plantar flexion** the heel is raised and the toes pointed downward. The range of plantar flexion is about  $55^\circ$ ; that of dorsiflexion is about  $35^\circ$ ; however, considerable variation occurs among different individuals. These movements take place around a *transverse axis*, which is slightly oblique and extends between the apex of the lateral malleolus to a point just distal to the medial malleolus. The malleoli tightly embrace the talus in all positions of the joint, so that any slight degree of side-to-side movement can occur only if the ligaments of the inferior tibiofibular joint are stretched and the fibula is bent. The superior articular surface of the talus is broader in front than behind. In dorsiflexion, therefore, greater space is required between the two malleoli. This is obtained by a slight lateral rotation of the lower end of the fibula, which is accomplished by a stretching of the ligaments of the inferior tibiofibular joint, thereby allowing a slight gliding at the tibiofibular articulation.

FIG. 5-77. The left ankle joint. Posterior aspect.

The deltoid ligament is of great strength, so much so that it usually resists a force powerful enough to fracture the process of bone to which it is attached. Its middle portion, together with the calcaneofibular ligament, binds the bones of the leg firmly to the foot, resisting displacement in every direction. Its anterior and posterior fibers assist in limiting plantar flexion and dorsiflexion. The posterior talofibular ligament assists the calcaneofibular in resisting the displacement of the foot backward, and deepens the cavity for the reception of the talus. The anterior talofibular is a security against the displacement of the foot forward, and helps limit plantar flexion of the joint.

**Muscles Producing Movements.** **Plantar flexion** of the foot is produced principally by the gastrocnemius, soleus, and plantaris, and to a lesser extent by the tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles. **Dorsiflexion** results from the action of the tibialis anterior, which is assisted by the peroneus tertius, extensor digitorum longus, and extensor hallucis longus.

**Clinical Interest.** A "sprained ankle" may result when the weight of the body is forcibly exerted upon the foot as it is inverted or everted. Most sprains are of the *inversion type*, which results in the tearing of ligaments at the lateral aspect of the ankle joint. In these instances the calcaneofibular as well as the anterior talofibular ligaments most often rupture, but a portion of the posterior talofibular ligament may also tear. *Eversion sprains* may rupture a portion of the deltoid ligament, but frequently the medial malleolus will fracture under these circumstances because of the great strength of the ligament.

## INTERTARSAL JOINTS

The intertarsal joints will be described in the following order:

- Subtalar (talocalcaneal) joint
- Talocalcaneonavicular joint
- Calcaneocuboid joint
- Transverse tarsal joint
- Ligaments connecting the calcaneus and navicular
- Cuneonavicular joint
- Cuboideonavicular joint
- Intercuneiform joints
- Cuneocuboid joint

**SUBTALAR (TALOCALCANEAL) JOINT.** Two articulations exist between the calcaneus and talus, an anterior and posterior. Because the anterior joint forms part of the talocalcaneonavicular joint, it will be described with that articulation.

The more posterior joint, the subtalar, is formed between the concave posterior calcaneal facet on the inferior surface of the talus, and the convex posterior facet on the superior surface of the calcaneus. It is a gliding joint, and the two bones are connected by an articular capsule and by anterior, posterior, lateral, medial, and interosseous talocalcaneal ligaments (Figs. 5-78; 5-79).

**Ligaments.** The articular capsule envelops the joint, and consists for the most part of short fibers that are split into distinct slips. Between these there is only a weak fibrous investment. A synovial membrane lines the capsule of the joint, and the joint cavity is distinct from all others in the foot because it has no intercommunicating channels.

The **anterior talocalcaneal ligament** extends from the anterior and lateral surface of the neck of the talus to the superior surface of the calcaneus (Fig. 5-79). It forms the posterior boundary of the talocalcaneonavicular joint and is sometimes described as the **anterior interosseous ligament**.

The **posterior talocalcaneal ligament** (Fig. 5-75) connects the lateral tubercle of the talus with the proximal and medial part of the calcaneus. It is a short band, and its fibers radiate downward to the calcaneus from their narrow attachment to the talus.

The **lateral talocalcaneal ligament** (Figs. 5-74; 5-76; 5-79) is a short, strong fasciculus, passing from the lateral surface of the talus immediately beneath its fibular facet to the lateral surface of the calcaneus. Its fibers course in the same direction as those of the calcaneofibular ligament, but it is placed on a deeper plane than that ligament.

The **medial talocalcaneal ligament** (Figs. 5-75; 5-80) connects the medial tubercle on the back of the talus with the sustentaculum tali. Its fibers blend with those of the plantar calcaneonavicular ligament.

The **cervical ligament** (Fig. 5-76) occupies the sinus tarsi, a small concavity on the anterolateral aspect of the foot between the talus and the calcaneus. The ligament is a strong band of fibers attached above to the inferolateral aspect of the neck of the talus and below to the upper surface of the calcaneus. The cervical ligament is important because it becomes taut during inversion, helping to prevent the foot from an excessive degree of that movement (Jones, 1944).

The **interosseous talocalcaneal ligament**

**FIG. 5-78.** Coronal section through right talocrural and talocalcaneal joints showing the interosseous talocalcaneal ligament and the relationship of structures coursing beneath the malleoli.

**FIG. 5-79.** Talocalcaneal and talocalcaneonavicular articulations exposed from above by removing the talus.

**Fig. 5-80.** The subtalar and talocalcaneonavicular joints of the right foot viewed from above. The talus has been removed from the joint cavity and rotated medially to expose its inferior articular surfaces. Inversion and eversion of the foot occurs around the indicated axis. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban and Schwarzenberg, Munich, 1980).

(Figs. 5-74; 5-78; 5-79; 5-82) forms the chief bond of union between the talus and calcaneus. It is, in fact, a portion of the united capsules of the talocalcaneonavicular and the talocalcaneal joints, and consists of two partially united layers of fibers, one belonging to the former and the other to the latter joint. It is attached to the groove between the articular facets on the distal surface of the talus, and to a corresponding depression on the proximal surface of the calcaneus. It is thick and strong, being at least 2.5 cm in breadth from side to side, and serves to bind the calcaneus and talus firmly together.

**TALOCALCANEONAVICULAR JOINT.** This articulation is a compound, multiaxial, synovial joint of the spheroid type. The rounded head of the talus is received into a concavity or socket (Fig. 5-79) formed by two bones, the posterior surface of the navicular, the anterior articular surface of the calcaneus, and two ligaments, the plantar calcaneonavicular (spring) ligament medially, and the calcaneonavicular part of the bifurcated ligament laterally. These bony and ligamentous structures are all surrounded by an articular capsule. Dorsally, the joint is reinforced by the dorsal talonavicular ligament. At this point only the articular capsule and (dorsal) talonavicular ligament will be described.

**Ligaments.** The **articular capsule** is imperfectly developed on the plantar aspect of the joint because of the ligamentous and bony socket. However, posteriorly it is considerably thickened and forms the anterior component of the strong interosseous talocalcaneal ligament which fills the sinus tarsi, formed by the opposing grooves on the calcaneus and talus. A synovial membrane lines the inner aspect of the capsule of this joint.

The **(dorsal) talonavicular ligament** (Figs. 5-75; 5-76) is a broad, thin band that connects the neck of the talus to the dorsal surface of the navicular bone. Medially, it blends with the ligament of the deltoid, and it is covered by the extensor tendons.

The plantar calcaneonavicular ligament and the calcaneonavicular part of the bifurcated ligament form the plantar and lateral ligaments of this joint.

**Movements.** The subtalar (talocalcaneal) and talocalcaneonavicular joints permit a considerable range of gliding and rotation. The movements at these joints (not to be confused with those at the ankle joint) result in inversion or eversion of the plantar surface of the foot.

**Inversion** of the foot is a movement in which the medial border of the foot is raised and the lateral border lowered, so that the sole of the foot is turned medially. In **eversion** the lateral border is raised and

the medial border is lowered, and as a result the sole of the foot is turned laterally. The greatest range of inversion and eversion occurs at the subtalar joint, and usually inversion is combined with some degree of plantar flexion and adduction, whereas eversion is frequently associated with dorsiflexion and abduction. These movements can be performed either with the foot off the ground or with the weight of the body transmitted to the foot, as in walking along a surface that is sloped sideways or in turning quickly, which requires a leaning of the legs to the side while the sole of the foot is flat on the ground. The axis around which inversion and eversion occur is an oblique line approximately between the centers of the subtalar and talocalcaneonavicular joints. The axis passes from the dorsomedial side of the foot, plantarward, backward, and laterally to emerge on the lateral aspect of the heel (Fig. 5-80).

**Muscles Producing Movements.** *Inversion* is produced by the tibialis anterior and tibialis posterior muscles, assisted by the extensor and flexor hallucis longus muscles. *Eversion* results from the action of the peroneus longus and brevis muscles.

**CALCANEOCUBOID JOINT.** This joint resembles a saddle joint, but does not have the usual freedom of movement of such a joint. Its articular surfaces are reciprocally concavoconvex, with the distal (anterior) surface of the calcaneus forming the concave saddle that receives the convex proximal (posterior) border of the cuboid (Fig. 5-82). Five ligaments connect the calcaneus with the cuboid: the articular capsule, the dorsal calcaneocuboid, the calcaneocuboid portion of the bifurcated ligament, the long plantar, and the plantar calcaneocuboid.

**Ligaments.** The articular capsule of the calcaneocuboid joint completely surrounds the joint, but it is an imperfectly developed investment, containing certain strengthened bands which form the other ligaments of the joint.

The **dorsal calcaneocuboid ligament** is a thin but broad fasciculus which passes between the contiguous surfaces of the calcaneus and cuboid on the dorsal surface of the joint (Figs. 5-76; 5-80).

The **bifurcated ligament** (Figs. 5-76; 5-79; 5-80) is a strong band, attached behind to the upper anterior surface of the calcaneus. The ligament courses anteriorly, and divides into two parts: calcaneocuboid and calcaneonavicular. The **calcaneocuboid part** is fixed to the dorsomedial aspect of the cuboid and forms one of the principal bonds between the first and second rows of the tarsal bones. The **calcaneonavicular part** is attached to the dorsolateral surface of the navicular.

The **long plantar ligament** (Figs. 5-75; 5-76; 5-81) is the longest of all the ligaments of the tarsus. It is attached posteriorly to the plantar surface of the calcaneus in front of the calcaneal tuberosity. Anteriorly, its deep fibers stretch to the tuberosity on the plantar surface of the cuboid bone, while its more superficial fibers are continued distally to the bases of the second, third, fourth, and fifth metatarsal bones. These anteriorly extending fibers of the long plantar ligament convert the groove on the plantar surface of the cuboid into a canal for the tendon of the peroneus longus muscle. By extending nearly the entire length of the plantar surface of the lateral longitudinal arch, the strong, long plantar ligament reinforces that arch, and helps prevent its flattening.

The **plantar calcaneocuboid ligament** (Fig. 5-81) is sometimes called the short plantar ligament. It lies nearer the bones, or deep to the long plantar ligament, from which it is separated by a little areolar tissue. It is a short but wide band of great strength which extends from the plantar aspect of the anterior tubercle of the calcaneus and the depression in front of it to the plantar surface of the cuboid bone, behind the peroneal groove.

**Movements.** The movements permitted at the calcaneocuboid joint are principally of a gliding and rotational nature, and they accommodate the movements in the subtalar and talocalcaneonavicular joints during inversion and eversion of the foot.

**TRANSVERSE TARSAL JOINT.** The transverse tarsal joint is a collective term used for the combined calcaneocuboid and talonavicular part of the talocalcaneonavicular joints, because together their joint cavities extend in an irregular transverse plane across the foot. Although the two joint cavities do not communicate, a slight degree of dorsiflexion and plantar flexion of the anterior part of the foot is permitted along this transverse tarsal plane. At the same time, the sole of the foot is slightly inverted or everted. The bones anterior to the transverse tarsal joint are the cuboid and navicular, while those behind it are the calcaneus and talus.

**LIGAMENTS CONNECTING THE CALCANEUS AND NAVICULAR.** Although the calcaneus and navicular do not articulate directly, they are connected by two ligaments: the calcaneonavicular part of the bifurcated, and the plantar calcaneonavicular.

**Fig. 5-81.** Ligaments of the sole of the foot, with the tendons of the peroneus longus, tibialis posterior, and tibialis anterior muscles.

The **calcaneonavicular part of the bifurcated ligament**, already described, attaches the anterior part of the calcaneus to the adjacent lateral surface of the navicular bone.

The **plantar calcaneonavicular ligament** (Figs. 5-75; 5-81), commonly called the **spring ligament**, is a broad and thick band of fibers that connects the anterior margin of the sustentaculum tali of the calcaneus to the plantar surface of the navicular. This ligament not only serves to connect the calcaneus and navicular, but supports the head of the talus, forming part of the articular socket into which it is received. The *dorsal* surface of the ligament presents a fibrocartilaginous facet, lined by synovial membrane, upon

which a portion of the head of the talus rests. Its *plantar* surface is supported by the tendon of the tibialis posterior medially, and the tendons of the flexor hallucis longus and flexor digitorum longus laterally. These tendons augment the supporting function of the ligament. Its *medial* border is blended with the anterior part of the deltoid ligament of the ankle joint.

**Clinical Interest.** The plantar calcaneonavicular ligament, by supporting the head of the talus, is principally concerned in maintaining the medial longitudinal arch of the foot. When it yields, the head of the talus is pressed medially and distally by the weight of the body, and the foot becomes pronated, everted, and turned lateralward, exhibiting the con-

dition known as *flat-foot*. This ligament contains considerable numbers of elastic fibers, in order to give elasticity to the arch and spring to the foot. Hence, it is sometimes called the **spring ligament**. It is supported, on its plantar surface, by the tendon of the *tibialis posterior*, which spreads out at its insertion into a number of fasciculi, to be attached to most of the tarsal and metatarsal bones.

**CUNEONAVICULAR JOINT.** The convex distal (anterior) articular surface of the navicular bone is joined to the concave proximal (posterior) surfaces of the three cuneiform bones (Fig. 5-83). The navicular surface is characterized by three facets into which the cuneiform bones fit.

**Ligaments.** The joint is surrounded by an articular capsule within which a continuous synovial cavity extends across the joint, as well as between the adjacent cuneiform bones (Fig. 5-82). The joint cavity also extends distally between the lateral cuneiform and the cuboid. In addition to the capsule, both dorsal and plantar cuneonavicular ligaments interconnect the bones.

The **dorsal cuneonavicular ligaments** (Figs. 5-75; 5-76) are three small bundles, one attached to each of the cuneiform bones. The bundle connecting the navicular with the medial cuneiform is continuous around the medial side of the articulation with the plantar ligament which unites these two bones.

The **plantar cuneonavicular ligaments** are arranged similarly to the dorsal ligaments. They are stronger bands than the dorsal, which are reinforced by slips from the tendon of the *tibialis posterior* (Fig. 5-81).

**CUBOIDEONAVICULAR JOINT.** The rounded lateral surface of the navicular bone is joined to the posterior part of the medial surface of the cuboid. At times the joint contains a synovial cavity which is continuous with that of the cuneonavicular joint, but more often it is a fibrous joint of the syndesmosis type (Fig. 5-82). The two bones are interconnected by dorsal, plantar, and interosseous ligaments.

**Ligaments.** The **dorsal cuboideonavicular ligament** (Fig. 5-76) extends obliquely for-

**Fig. 5-82.** Oblique section of left intertarsal and tarsometatarsal articulations, showing the synovial cavities.

ward and laterally from the navicular to the cuboid bone on their dorsal surfaces.

The **plantar cuboideonavicular ligament** (Fig. 5-81) passes nearly transversely between the cuboid and navicular bones on their plantar surfaces.

The **cuboideonavicular interosseous ligament** (Fig. 5-82) consists of strong transverse fibers interconnecting the rough nonarticular portions of the adjacent lateral surface of the cuboid and medial surface of the navicular bones.

**INTERCUNEIFORM JOINTS.** The three cuneiform bones are united by two synovial intercuneiform joints (Fig. 5-82). Each of the two joints interconnects adjacent surfaces of the bones, the intermediate cuneiform being placed between the medial and lateral cuneiform bones. Their synovial cavities are continuous with that of the cuneonavicular joint. The joints are connected by dorsal, plantar, and interosseous ligaments.

**Ligaments.** The **dorsal intercuneiform ligaments**, two in number, are weak transverse bands. One connects the medial with the intermediate cuneiform and the other, the intermediate with the lateral cuneiform.

The **plantar intercuneiform ligaments** are arranged on the plantar surface similarly to those on the dorsal surface. They are stronger than the dorsal ligaments and are reinforced by slips from the tendinous insertion of the tibialis posterior muscle.

The **intercuneiform interosseous ligaments**, also two in number, consist of strong transverse fibers that pass between the rough nonarticular portions of the adjacent surfaces of the bones (Fig. 5-82). They are strong, deeply placed, fibrous ligaments which extend between the bones nearly the entire length of their apposed borders.

**CUNEOCUBOID JOINT.** This joint connects the smooth rounded lateral border of the lateral cuneiform bone with the adjacent medial border of the cuboid. Its small synovial cavity usually opens posteriorly into the cuneonavicular joint (Fig. 5-82). Similar to the intercuneiform joints, the cuneocuboid joint is interconnected by dorsal, plantar, and interosseous ligaments.

The **dorsal cuneocuboid ligament** is a relatively weak transverse band extending from the dorsal surface of the lateral cuneiform to the cuboid.

The **plantar cuneocuboid ligament** is considerably stronger than the dorsal and ex-

tends transversely between the lateral cuneiform and the cuboid bones on their plantar surfaces. A slip from the tendon of the tibialis posterior muscle may strengthen the ligament.

The **interosseous cuneocuboid ligament** is the strongest bond between the two bones. Its transverse fibers are deeply placed between the apposed borders of the bones in a manner similar to those of the intercuneiform ligaments (Fig. 5-82).

**Movements.** The cuneonavicular, cuboideonavicular, intercuneiform, and cuneocuboid joints permit slight gliding and rotational movements. These assist the more proximal intertarsal joints during inversion and eversion of the foot, and assist the bare foot especially to achieve a firmer grasp when necessary. The synovial cavities of all these joints are usually intercommunicating, and their ligaments help in the maintenance of the transverse arch of the foot.

#### TARSOMETATARSAL JOINTS

These are gliding joints. The bones entering into their formation are the medial, intermediate, and lateral cuneiforms, and the cuboid, which articulate with the bases of the five metatarsal bones. The **first metatarsal** bone articulates with the anterior surface of the medial cuneiform. The **second metatarsal** is wedged between the medial and lateral cuneiforms. It articulates medially with the lateral side of the medial cuneiform, by its base with the intermediate cuneiform, and laterally with the medial side of the lateral cuneiform. The **third metatarsal** articulates with the lateral cuneiform bone. The **fourth metatarsal** articulates with the cuboid and lateral cuneiform bone. The **fifth metatarsal** articulates only with the cuboid (Fig. 5-83).

Although five metatarsal bones articulate with four tarsal bones (the cuboid and the three cuneiforms), only three joint cavities are formed (Fig. 5-82). Medially, the joint between the first metatarsal and the medial cuneiform has its own distinct synovial sac. This **medial tarsometatarsal joint cavity** usually lies more distal to the others and is separated from them by an interosseous ligament which connects the medial cuneiform to the second metatarsal (Fig. 5-82). The **intermediate tarsometatarsal joint cavity** is found between the intermediate and lateral cuneiforms and the second and third metatarsal

**FIG. 5-83.** Adult foot. 1, Tuberosity of navicular bone, partly obscured by the shadow of the head of the talus. 2, Cuneonavicular joint. 3, Joint between metatarsal III and the lateral cuneiform bone. 4, Joint between metatarsal II and the intermediate cuneiform bone. 5, Joint between metatarsal I and the medial cuneiform bone.

bones. This cavity is continuous proximally with those of the intercuneiform joints and often with the cavity of the cuneonavicular joint. Additionally, two prolongations of the cavity extend distally (forward), one between the adjacent sides of the second and third metatarsal bones and the other between the sides of the third and fourth metatarsals. The **lateral tarsometatarsal joint cavity** has a distinct synovial sac between the cuboid and the bases of the fourth and fifth metatarsal bones. This cavity is also prolonged forward between the fourth and fifth metatarsals, but is separated from the intermediate joint cavity by an interosseous ligament which connects the lateral cuneiform and the base of the fourth metatarsal bone.

The bones are connected by dorsal and plantar tarsometatarsal ligaments and by interosseous cuneometatarsal ligaments.

**Ligaments.** The **dorsal tarsometatarsal ligaments** are strong, flat bands which pass between the adjacent surfaces of the tarsal and metatarsal bones on their dorsal aspect (Fig. 5-76). The first metatarsal is joined to the medial cuneiform by a thin articular

capsule (Fig. 5-75). To the dorsal surface of the second metatarsal are attached three bands, one from each cuneiform bone. The third metatarsal has one dorsal ligament, and this attaches to the lateral cuneiform. The fourth receives one from the lateral cuneiform and one from the cuboid; and the fifth, one from the cuboid.

The **plantar tarsometatarsal ligaments** consist of longitudinal and oblique bands disposed with less regularity than the dorsal ligaments. Those for the first and second metatarsals are the strongest (Fig. 5-81). The second and third metatarsals are joined by oblique bands to the medial cuneiform, while the fourth and fifth metatarsals are connected by a few fibers to the cuboid. The articulation of the medial cuneiform and the first metatarsal (tarsometatarsal joint of the large toe) is reinforced by the insertion of the peroneus longus tendon laterally and that of the tibialis anterior medially. Additionally, strands from the tendon of the tibialis posterior muscle strengthen the plantar surfaces of the tarsometatarsal joints of the second, third, and fourth toes, while the

long plantar ligament, as well, helps support the third and fourth tarsometatarsal joints by passing across their plantar aspect.

The **interosseous cuneometatarsal ligaments** are three in number. The first is constant and is the strongest, passing from the lateral surface of the medial cuneiform to the adjacent angle of the second metatarsal (Fig. 5-82). The second, which is the smallest and is less constant, passes from the lateral cuneiform to the lateral aspect of the second metatarsal. The third connects the lateral angle of the lateral cuneiform with the adjacent side of the base of the fourth metatarsal.

**Movements.** The movements permitted at the tarsometatarsal joints are limited to slight gliding of the bones upon each other. These joints, along with the others in the anterior part of the foot, move as a unit at the transverse tarsal joint, allowing the forepart of the foot a degree of rotatory movement which might be called supination and pronation in contrast to the inversion and eversion seen at the subtalar and talocalcaneonavicular joints.

**Nerve Supply.** The intertarsal and tarsometatarsal joints are supplied by the medial and lateral plantar nerves on their plantar aspect and by the deep peroneal nerve on their dorsal aspect.

## INTERMETATARSAL JOINTS

**JOINTS BETWEEN THE BASES OF THE METATARSAL BONES.** Even though the base of the first metatarsal bone lies adjacent to the proximal part of the shaft of the second metatarsal, there are no ligaments between the bones, but a bursa is frequently found at this site. In contrast, the bases of the second and third, third and fourth, and fourth and fifth metatarsals are interconnected by dorsal, plantar, and interosseous intermetatarsal ligaments.

**Ligaments.** The dorsal intermetatarsal ligaments pass transversely between the dorsal surfaces of the bases of the adjacent four lateral metatarsal bones.

The **plantar intermetatarsal ligaments** (Fig. 5-81) are strong bands that connect the bases of the bones on the plantar surface in a pattern similar to the dorsal intermetatarsal ligaments.

The **interosseous intermetatarsal ligaments** are usually three in number and consist of strong transverse fibers that connect the rough nonarticular portions of the adjacent surfaces of the bases of the lateral four metatarsal bones.

**Synovial Membranes** (Fig. 5-82). The synovial membranes between the bases of the second and third and the third and fourth metatarsal bones are continuous with that of the intermediate tarsometatarsal joint cavity. The synovial cavity between the fourth and fifth metatarsals is a prolongation of the lateral tarsometatarsal joint cavity (Fig. 5-82).

**Movements.** The movement permitted between the tarsal ends of the metatarsal bones is limited to a slight gliding of the articular surfaces upon one another. This allows for an elevation or a slight widening of the transverse arch, adding some flexibility to the forepart of the foot.

**UNION OF THE HEADS OF THE METATARSAL BONES.** The heads of all the metatarsal bones are interconnected on their plantar aspect by the deep transmetatarsal ligaments.

**Ligaments.** The **deep transverse metatarsal ligaments** are four short, narrow bands which course across and interconnect the heads of all the metatarsal bones on their plantar surfaces. They blend anteriorly with the plantar (glenoid) ligaments of the metatarsophalangeal joints. Along their concave plantar surfaces in the middle of each toe course the tendons of the long flexors. Between the toes, the plantar surfaces of the ligaments are in contact with the lumbrical muscles and the digital vessels and nerves. The dorsal surfaces of the ligaments are in relation to the interosseous muscles whose tendons course along both sides of the metatarsophalangeal joints of the four lateral toes. The deep transverse metatarsal ligaments differ from the deep transverse metacarpal ligaments in that the first metatarsal is connected to the second, whereas in the hand, the first metacarpal is not attached by means of a deep metacarpal ligament.

**SYNOVIAL CAVITIES OF THE TARSAL AND TARSOMETATARSAL JOINTS** (Fig. 5-82). Six synovial cavities are found in the articulations of the tarsus and metatarsus: *one* for the subtalar joint; a *second* for the talocalcaneonavicular joint; a *third* for the calcaneocuboid joint; a *fourth* for the cuneonavicular, intercuneiform, and cuneocuboid joints, and the articulations of the intermediate and lateral cuneiforms with the bases of the second and third metatarsal bones, and the adjacent surfaces of the bases of the second, third, and fourth metatarsal bones; a *fifth* for the joint between the medial cuneiform and the metatarsal bone of the great toe; and a *sixth* for the articulation of the cuboid with the fourth and fifth metatarsal bones. A small synovial cavity is sometimes found between the contiguous surfaces of the navicular and cuboid bones.

### METATARSOPHALANGEAL JOINTS

The metatarsophalangeal articulations may be considered ellipsoid in type and are formed by the reception of the oval rounded heads of the metatarsal bones in shallow cavities on the bases of the proximal phalanges. A loose fibrous capsule lined with a synovial membrane surrounds the metatarsophalangeal joint on each toe. The capsule is reinforced by a plantar ligament and two collateral ligaments. The dorsal surface of the capsule is thin, but it is strengthened by expansions from the extensor tendons.

**Ligaments.** The **plantar ligaments**, sometimes called **glenoid ligaments**, are thick, dense, fibrous structures. They are placed on the plantar surfaces of the joints in the intervals between the collateral ligaments, to which they are connected. They are loosely united to the metatarsal bones, but firmly attached to the bases of the first phalanges. Their plantar surfaces are intimately blended with the deep transverse metatarsal ligaments, and in addition, they are grooved for the passage of the flexor tendons, whose sheaths are connected to the sides of the grooves. The deep surfaces of the plantar ligaments form part of the articular facets for the heads of the metatarsal bones, and are lined by synovial membrane. Two sesamoid bones lie in the plantar ligament of the large toe.

The **collateral ligaments** are strong fan-shaped bands placed on both sides of each metatarsophalangeal joint. Each ligament is attached by one end to the posterior tubercle on the side of the head of the metatarsal bone and, by the other, to the contiguous extremity of the phalanx.

**Movements.** The movements permitted in the metatarsophalangeal articulations are *flexion*, *extension*, *abduction*, and *adduction*. Flexion is freer than extension and hence has a greater range. Flexion is limited by the extensor tendons and their expansions, whereas extension is limited by the flexor tendons and the plantar ligaments. Abduction and adduction are referenced to a line passing through the second toe.

### INTERPHALANGEAL JOINTS

The interphalangeal joints of the toes are ginglymus or hinge joints. The distal surface of the proximal bone at each joint resembles

a pulley, and the proximal surface of each distal bone has a reciprocally curved double concavity that fits in the pulley. The phalanges of the toes are smaller than those in the fingers, and frequently the joints between the middle and distal phalanges in the more lateral toes are ankylosed and nonfunctional.

**Ligaments.** Each joint has an articular capsule, a plantar and two collateral ligaments. The arrangement of these ligaments is similar to that in the metatarsophalangeal articulations. The extensor tendons and their dorsal expansions replace the dorsal ligaments.

**Movements.** The only movements permitted in the joints of the digits are flexion and extension. These movements have a greater range between the proximal and middle phalanges than between the middle and distal. The degree of flexion is quite considerable, but extension is limited by the flexor tendons and the plantar ligaments.

## Arches of the Foot

The bones of the foot, their interconnecting ligaments, and the musculature are arranged in a manner consistent with the important functions of support, weight distribution, and locomotion of the body. An imprint of a wet foot on a floor shows that the heel, the lateral margin, the region beneath the heads of the metatarsal bones (the ball of the foot), and the pads of the distal phalanges touch the floor, whereas the medial margin of the foot is arched and does not touch the floor. The bony substructure of this **medial longitudinal arch**, when visualized on the articulated skeleton of the foot, is seen to consist of the calcaneus, talus, navicular, the three cuneiform bones, and the associated three medial metatarsal bones. The concavity of the medial arch is supported on two pillars, a posterior or calcaneal pillar, and an anterior or metatarsal pillar which consists of the heads of the first, second, and third metatarsal bones. The flatter **lateral longitudinal arch**, parallel to the medial, is composed also of the calcaneus posteriorly, the cuboid bone, and the fourth and fifth metatarsal bones anteriorly. Its posterior pillar is the calcaneal tuberosity and its anterior pillar consists of the heads of the lateral two metatarsal bones (Figs. 5-84; 5-85).

FIG. 5-84. Bones on the medial aspect of the foot. Observe the concave medial longitudinal arch.

The stability of the medial longitudinal arch is dependent, to a large extent, on the functional integrity of the plantar aponeurosis and its subjacent long plantar and plantar calcaneonavicular (or spring) ligaments. However, the muscles are also of importance in maintaining the medial arch during locomotion. These especially include the tendon of the flexor hallucis longus, along with the flexor digitorum longus, the tibialis posterior, and the intrinsic foot muscles. In the static standing position, however, electromyographic studies have shown that these muscles are relatively inactive.

The lateral longitudinal arch transmits weight to the ground along the lateral aspect of the foot, but the height of its arch is lower than the medial. Its slighter concavity is supported by the lateral part of the long plantar ligament along with the plantar calcaneocuboid (short plantar) ligament. Additionally, the peroneus longus muscle and the plantar muscles on the lateral aspect of the sole of the foot help maintain the integrity of the

lateral arch. It has been stated that some special difference in function is served by the two longitudinal arches. The greater curvature, resiliency, and elasticity of the medial arch is believed to be of more importance in sustaining marked and immediate forces, such as those received during jumping. The more slightly curved lateral arch is less elastic as well, and is constructed to transmit thrust and weight to the ground, in contrast to the medial arch which absorbs such forces. The lateral arch appears to serve a more significant role in walking and running.

In addition to being arched longitudinally, the foot is also arched transversely. Actually, each foot forms half a transverse dome which is completed when the two feet are placed side by side. The more proximal **transverse** or **metatarsal arch** is formed by the navicular, the three cuneiforms, the cuboid, and the bases of the five metatarsal bones. The maintenance of the transverse arch is more importantly due to ligaments

FIG. 5-85. Bones on the lateral aspect of the foot. Observe that the concavity of the lateral longitudinal arch is less pronounced than that of the medial arch shown in Figure 5-84.

and tendons which bind the cuneiforms and the bases of the metatarsal bones together, than to the construction of the bony parts. The tendon of the peroneus longus muscle is of particular significance in the integrity of the transverse arch, because it stretches across the arch and tends to approximate the bones. More distally the heads of the metatarsal bones form a shallow but complete transverse arch in each foot. These latter arches are maintained by the deep transverse metatarsal ligaments.

**Clinical Interest.** The most common abnormality of the foot is a flattening of its plantar surface. In **flat foot**, the weight becomes distributed over the entire plantar surface, because the contour of the medial longitudinal arch (and consequently also the transverse arch) is lost. This depression of the medial arch is brought about by stretching the ligamentous connections at the talonavicular and cuneonavicular joints. As these ligaments become incompetent, the head of the talus pushes the soft plantar tissues to the ground, thereby flattening the medial longitudinal arch.

## Muscles and Fasciae

Contractility, a fundamental property characteristic of protoplasm, is especially well developed in cells of muscular tissue. Aggregations of these cells in various parts of the body form the **muscles**. These structures are capable of contracting, and muscles are responsible not only for voluntary motion, such as that of the limbs, but also for the contractions of the heart as well as the less obvious movements of the viscera. This chapter deals with the somatic muscles. Cardiac muscle and the visceral muscles of internal organs will be discussed in subsequent chapters.

The ability to move provides organisms with a means of reacting to the environment. The contractions of somatic muscles are made mechanically effective by means of the tendons, aponeuroses, and fasciae, which secure the ends of the muscles and control the direction of their pull. Many muscles are attached to bones, but others, such as the superficial muscles of the face, have no connections to the skeleton. Muscles of the limbs and trunk underlie the skin and

fascial layers, giving substance and contour to these regions. Muscle tissue accounts for approximately 40% of the body weight, and the individual muscles vary greatly in size. The gastrocnemius forms the bulk of the calf of the leg; the sartorius is nearly 61 cm in length; and the stapedius, a tiny muscle of the middle ear, weighs 0.1 gm and is 2 to 3 mm in length.

Somatic muscles have also been called **voluntary, skeletal, or striated** muscles, although these terms are not always appropriate. Examples of somatic muscles that are not under complete voluntary control are found in the pharynx and upper esophagus; some somatic muscles, such as certain facial muscles, are not attached to the skeleton, and both visceral and cardiac muscles show striations. In general, however, most somatic muscles are under voluntary control, are attached to skeletal structures, and show prominent longitudinal and cross striations.

### Development of Muscles

Most muscles throughout the body, with the exception of a few that are of ectodermal origin, arise from mesoderm. The intrinsic muscles of the trunk are derived from the myotomes, while the muscles of the head and limbs differentiate directly from the mesoderm.

**MUSCLES DERIVED FROM MYOTOMES.** The intrinsic muscles of the trunk, which are derived directly from the myotomes, are conveniently treated in two groups, the deep muscles of the back and the thoracoabdominal muscles.

The **deep muscles of the back** extend from the sacral to the occipital region and vary much in length and size. They act chiefly on the vertebral column. The shorter muscles, such as the interspinales, intertransversarii, the deeper layers of the multifidus, the rotatores, levatores costarum, obliquus capitis inferior, and obliquus capitis superior, which extend between adjoining vertebrae, and the rectus capitis posterior minor, which extends between the adjoining atlas and occipital bone, all retain the primitive segmental character of the myotomes. Other muscles, such as the splenius capitis, splenius cervicis, sacrospinalis, erector spinae, superficial and intermediate layers of the multifidus, iliocostalis, longissimus, spinales,

semispinales, and rectus capitis posterior major, which extend over several vertebrae, are formed by the fusion of successive myotomes and then split into longitudinal columns. A thick fascial plane, the thoracolumbar fascia, develops between these true myotomic muscles and the more superficial ones which migrate over the back, such as the trapezius, the rhomboids, and the latissimus dorsi.

The **anterior vertebral muscles**—the longus colli, longus capitis, rectus capitis anterior, and rectus capitis lateralis—are derived from the ventral part of the cervical myotomes, as are probably also the scalenes.

The **thoracoabdominal muscles** arise through the ventral extension of the thoracic myotomes into the body wall. This process takes place coincidentally with the ventral extension of the ribs. In the thoracic region the primitive myotomic segments persist as the intercostal muscles, but over the abdomen these ventral myotomic processes fuse into a sheet that splits in various ways to form the rectus abdominis, the external and internal oblique, and the transversus. Such muscles as the pectoralis major and minor and the serratus anterior do not belong to the aforementioned group.

**VENTROLATERAL MUSCLES OF THE NECK.** The intrinsic muscles of the tongue, the *infrahyoid muscles*, and the *diaphragm* are derived from a more or less continuous premuscle mass, formed by the **occipital myotomes**, which extends on each side from the tongue into the lateral region of the upper half of the neck. Into this developing mesoderm extend the hypoglossal nerves and branches of the upper cervical nerves. The two halves, which form the *infrahyoid muscles* and the *diaphragm*, are at first widely separated from each other by the heart. As the heart descends into the thorax, the diaphragmatic portion of each lateral muscle mass is carried with its phrenic nerve down into the thorax, while the laterally placed *infrahyoid muscles* move toward the midventral line of the neck.

**MUSCLES OF THE SHOULDER GIRDLE AND UPPER EXTREMITY.** The trapezius and sternocleidomastoid arise from a common premuscle mass in the occipital region just caudal to the last branchial arch. As the mass increases in size, it spreads caudally to the shoulder girdle to which it later becomes attached, and dorsally to the spinous pro-

cesses, gaining attachment on these at a still later period. The *levator scapulae*, *serratus anterior*, and the *rhomboids* arise from premuscle tissue in the lower cervical region and undergo extensive migration. The *latissimus dorsi* and *teres major* are associated in their origin from the premuscle sheath of the arm, as are also the two *pectoral muscles*, when the arm bud lies in the lower cervical region.

The remaining *intrinsic muscles* of the upper extremity develop *in situ* from mesoderm of the arm bud and probably do not derive cells or buds from the myotomes. The nerves to these muscles enter the arm bud when it still lies in the cervical region and, as the arm shifts caudally over the thorax, these cervical nerves unite to form the brachial plexus.

**MUSCLES OF THE LOWER EXTREMITY.** The muscles of the lower extremity, like those of the upper, develop *in situ* from the mesoderm of the leg bud, the myotomes apparently taking no part in their formation.

**MUSCLES OF THE HEAD.** The *extraocular muscles* in the orbit arise from the mesoderm over the dorsal and caudal sides of the optic stalk. This mesenchyme gives rise to what may be called three *preotic myotomes*, each of which is supplied by its own cranial nerve (oculomotor, trochlear, and abducens). The muscles of mastication arise from the mesoderm of the **mandibular arch**. The mandibular division of the trigeminal nerve enters this premuscle mass before the temporal, masseter, and pterygoid muscles split to develop as separate structures. The *facial muscles of expression* arise from the mesoderm of the **hyoid arch**. The facial nerve enters this mass before the individual muscles begin to differentiate, and as the muscle mass spreads out over the face, head, and neck, it splits more or less incompletely into the various muscles.

**MUSCLE-NERVE MIGRATION.** Initial differentiation of the muscular system proceeds independently of the nervous system and only later does it appear that muscles require the functional stimuli of the nerves for their continued existence and growth. Owing to their early attachments to muscle rudiments, the nerves in a general way may indicate the position of origin of many of the muscles, and likewise, in many instances, the nerves reveal the paths along which the developing muscles have migrated during

development. The muscle mass that forms the diaphragm, for example, has its origin in the region of the fourth and fifth cervical segments. The phrenic nerve centers this developing mesoderm in the cervical region and is drawn out as the diaphragm migrates through the thorax. Likewise, the trapezius and sternocleidomastoid arise in the lateral occipital region as a common muscle mass, into which the accessory nerve grows at a very early period. As the muscle mass migrates and expands caudally, the nerve is carried with it. The pectoralis major and minor arise in the cervical region, receive their nerves while in this position and, as the muscle mass migrates and expands caudally over the thorax, the nerves are carried along. The latissimus dorsi and serratus anterior are excellent examples of migrating muscles whose nerve supply indicates their origin in the cervical region. The rectus abdominis and the other abdominal muscles also migrate or shift from a lateral to a ventrolateral or abdominal position, carrying with them the nerves.

The facial nerve, which at an early stage enters the common facial muscle mass of the second branchial or hyoid arch, migrates with the differentiating muscle as it spreads over the head, face, and neck. As the muscle mass splits into the various muscles of facial expression, the nerve is correspondingly split. Similarly, the mandibular division of the trigeminal nerve enters the muscle mass of the mandibular arch, and as this mass splits and migrates to form the muscles of mastication, the nerve splits into its various branches. The muscles supplied by the oculomotor nerve arise from a single mass in the orbital region, and the lingual muscles arise from a common mass supplied by the hypoglossal nerve. These examples show that the nerve supply may serve as a key to understanding the common origin of certain muscle groups.

## Fasciae

A number of noncontractile connective tissue elements are required to organize the contractile muscle fibers into effective mechanical structures. Large numbers of individual muscle fibers are bound together into fascicles by collagenous connective tissue septa, collectively called the **perimysium**.

Surrounding all the fascicles of a muscle is a thicker connective tissue layer, the **epimysium**. The ends of the muscle are attached to bones by tendons and aponeuroses, and individual muscles and groups of muscles are held in place and separated by connective tissue sheets called **fasciae**. The term fascia is used for the dissectible, fibrous connective tissues of the body other than specifically organized structures such as tendons, aponeuroses, and ligaments. In a more restricted sense, the term fascia also is used to indicate local connective tissue membranes that enclose a part of the body or invest organs. It should be appreciated that the fasciae are part of the general connective tissues which form a functional as well as morphological system in which the connective tissue varies in thickness, in density, in accumulation of fat, and in relative amounts of collagenous fibers, elastic fibers, and tissue fluids.

Three general types of fasciae are usually described: the **superficial fascia**, the **deep fascia**, and the **subserous fascia**. The superficial fascia is a loose, fat-filled layer which intervenes between the skin and the deep fascia. It is variable in thickness. The deep fascia is the principal somatic fascia which invests and penetrates between the various structures that form the body wall and the limbs. It is the most extensive of the three types, and occupies much of the dissector's time in the separation of anatomical structures. The subserous fascia lies within the body cavities, forming the fibrous layer of the serous membranes (pleura, pericardium, and peritoneum), which covers and supports the viscera and attaches the parietal layer of the serous membranes to the deep fascia of the internal surface of the body wall.

**SUPERFICIAL FASCIA.** The superficial fascia is continuous over the entire body between the skin and the deep fascial investment of the specialized structures of the body, such as muscles. It is composed of two layers. The outer one, sometimes called *panniculus adiposus*, normally contains an accumulation of fat that may be several centimeters thick or, in emaciated individuals, may be almost entirely lacking. Although the amount of fat and its distribution in the superficial fascia varies between individuals, generally it is somewhat more abundant in females. In certain regions of the body, such as the external nose, the auricle of the ear, the eyelids, the labia minora, the penis, and

the scrotum, the superficial fascia contains virtually no fat. The inner layer is a thin membrane that ordinarily has no fat, but contains a generous amount of elastic tissue. The two layers are quite adherent in most regions, but are separable by careful dissection, particularly in the lower anterior abdominal wall. Between the two layers frequently course the superficial arteries, veins, nerves, and lymphatics. The mammary glands, most of the facial muscles, the platysma muscle, as well as the dartos muscle of the scrotum, are all found in the superficial fascia. The superficial fascia acts as an insulator for the body and helps to prevent the loss of body heat.

In many parts of the body the superficial fascia glides freely over the deep fascia, producing the characteristic movability of the skin in a region such as the back of the hand. At these sites the superficial and deep fasciae can be dissected apart easily by a probing finger or blunt instrument, as they are separated by a *fascial cleft*. At certain other points on the body surface, especially over bony prominences, the two fasciae are closely adherent. They retain their individuality even at these sites, however, and are not continuous.

**DEEP FASCIA.** Deep to the superficial fascia is a dense stratum of fibrous tissue which immediately covers the muscles and is called the deep fascia. It consists of a rather intricate series of sheets and bands which hold the individual muscles and other structures in their proper relative positions, separating them for independent function as well as joining them together into an integrated whole. The intrinsic connective tissue of the capsules or stroma of these structures is not included in the definition of deep fascia. In the case of a muscle, the epimysium may be fused with the overlying deep fascia and even lose its identity, as in the triceps, or the epimysium may be separated from the deep fascia by a cleft and retain its individuality, as in the biceps brachii.

The sheets of deep fascia are organized into a continuous system and frequently attach to the periosteum of bones or the perichondrium of cartilage. The ligaments also may assist in establishing this continuity. On occasion a sheet of deep fascia may split in order to surround or invest muscles, only to unite again into a single sheet beyond the muscles. Splitting and fusing are important because in this manner any sheet

of fascia can be traced to other sheets and can be shown to make eventual attachment to the skeleton.

The mechanical function of fascia is particularly well developed in the deep fascia and is responsible for its many regional variations and specializations. A fascial sheet may be thickened, either for strength or padding. It may be fused with another sheet or split into several layers. It may be separated from another fascial sheet by a plane of cleavage, or several sheets may combine to form compartments for groups of muscles.

The thickening of a fascial sheet for greater strength, especially if it receives the direct pull of a muscle, occurs through the addition of parallel bundles of collagenous fibers which impart to it the white, glistening appearance of an aponeurosis. Deep fascia of this type may separate muscles of different functional groups by attaching along the longitudinal axis of a bone between the muscles. These fascial sheets are called **intermuscular septa**, and examples are shown in Figure 6-1, where the flexors in the arm (biceps brachii and brachialis) are separated both medially and laterally from the extensor (triceps) in this manner. At another site, a strengthened fascial sheet may cover a muscle and be used by it as a surface for attachment, for example, the **investing layer** of the forearm. An extreme instance is that of the fascia lata of the thigh, where the iliotibial band is in fact the principal tendon of insertion for the gluteus maximus and the tensor fasciae latae muscles.

A band of deep fascia may act as a ligament. This is the case with the greatly strengthened portion of the clavipectoral fascia called the costocoracoid membrane. By its attachment to the coracoid process and ribs, this membrane serves as a ligament for the articulations of the clavicle. Other specializations of the deep fascia are the annular ligaments and retinacula at the wrist and ankle which provide tunnels for the long tendons of the hand and foot.

At some sites a laminated fascial sheet may be thickened without a corresponding increase in strength. The fascia splits into two leaves which are separated by a pad of connective tissue containing fat and an occasional blood vessel or lymph node. An example of this is the lamination of the outer cervical fascia above the sternum which is called the suprasternal space.

A **fascial compartment** is a region of the

**FIG. 6-1.** Cross section through the right arm a little below the middle of the humeral shaft. Note the deep fascia of the arm and observe that the investing layer of brachial fascia surrounds the arm, while the medial and lateral intermuscular septa separate the flexor (biceps brachii and brachialis muscles) from the extensor (triceps brachii muscle) compartment.

body that is walled off by deep fascia. Characteristically, it contains a muscle or a group of muscles, but in some instances other structures are included. A typical example, described above, is the flexor and extensor compartments of the arm. The arm, enclosed by brachial fascia, is divided into two compartments by the medial and lateral intermuscular septa. In many descriptions of fascia, such compartments are ambiguously called spaces or potential spaces. For example, the mediastinum is sometimes called a "space" containing the heart, great vessels, esophagus, and other structures, whereas in reality it is a compartment enclosed by mediastinal fascia.

The **fascial cleft**, an important specialization, is a cleavage that separates two contiguous fascial surfaces. At times it is a stratum rich in fluid but poor in traversing fibers, allowing the two fascial surfaces to move more or less freely and making separation easy at dissection. The degree of separation may vary from an almost complete detachment to a comparatively strong adhesion, apparently depending on the need for motion between the parts. The cleft between the superficial fascia and the deep fascia has

already been mentioned. The cleft between a muscle and an overlying, restraining fascial layer, like the biceps brachii and brachialis fascia, actually separates the epimysium of the muscle and the true fascial sheet. The cleft between two adjacent muscles is likely to separate the epimysium of each muscle, but the latter may, in some places, be thickened into a true fascial sheet.

A **bursa** is a specialized structure that allows an efficient freedom of motion between contiguous connective tissue surfaces. It is a relatively small, circumscribed pocket of complete separation, the lining of which provides two opposed, lubricated surfaces similar to the synovial membranes of a joint. When a tendon must glide freely immediately adjacent to bone, a bursa is characteristically interposed between the tendon and the periosteum. The **synovial tendon sheaths** of the hand and foot are highly specialized bursae.

Just as there are adaptations of deep fascia for the separation of structures, there are also fascial adaptations for structural attachments. Different deep fascial sheets may fuse with each other, as is the case with the outer investing and middle cervical fasciae

near the hyoid bone. They may attach to bones, as the clavipectoral fascia to the clavicle. The attachment in some instances is secure, but in others it is loose. Thus, the relationship between two contiguous fascial layers may vary from the complete separation at a bursa, or the functional separation of a fascial cleft, through progressive degrees of adhesion and attachment, including complete fusion.

Fascial sheets are named most commonly and most appropriately for the regions of the body that they occupy or the structures that they cover. For example, the *brachial fascia* encloses the arm and the *deltoid fascia* covers the deltoid muscle. Some fasciae have descriptive names, such as the *fascia lata* from its broad extent on the thigh or the *fascia cribrosa* from its many openings. A few are named from their attachments, for example, the *clavipectoral fascia* and the *coracoclavicular fascia*.

A more detailed description of the various fascial structures of different regions is included with the discussions of the appropriate muscle groups and organs.

## Form and Attachments of Muscles

There is a considerable variation in the manner by which muscle fibers are arranged to form whole muscles. The different architectural types of muscle are adapted so that the arrangement and shape of the fasciculi best meet the direction and force required of the contracted muscle as it functions. Although there are many muscle forms and shapes, certain general categories can be identified.

**STRUCTURAL TYPES OF MUSCLES.** The arrangement of the fasciculi and the manner in which they approach their tendons are used as a means of classifying muscles. The following types will be described: **parallel**, **fusiform**, **oblique**, **triangular**, and **overlapping** (crossed and spiral).

**Parallel Muscle.** In this simplest arrangement the muscle fibers are parallel with the longitudinal or transverse axis of the muscle and terminate at the ends in flat tendons (Fig. 6-2). These muscles may be short and flat like the thyrohyoid, somewhat longer and

straplike as are the sternothyroid and sternohyoid, long and narrow like the sartorius, or broad and relatively thin like the rhomboid major. The individual muscle fibers may course the entire length of the muscle or may interdigitate into **tendinous intersections**, such as is seen in the rectus abdominis and semispinalis capitis muscles.

**Fusiform Muscle.** In some muscles the fleshy portion is rounded in the center and tapering at the ends to form a spindle shaped belly which terminates in a tendon at one or both ends. These fusiform muscles (Fig. 6-2) may have a single belly (lumbricals or biceps brachii: one belly from two heads) or two bellies interrupted by a tendon (diaphragm and omohyoid muscles).

**Oblique Muscle.** In many muscles a tendon courses for considerable distances either within the muscle or along its surface. In these muscles the fibers attach obliquely to the tendon like the plumes of a feather, and the muscles are therefore considered to be **pennate** (feather-like) in their construction. If the muscle fibers converge obliquely on one side of the tendon, the muscle is called **unipennate**, but should be called **semipennate** (flexor pollicis longus in the hand and extensor digitorum longus and peroneus tertius in the leg). If the fleshy muscle fibers arise from a broader area and attach obliquely from several sides to a centrally placed tendon, the muscle is considered to be a **bipennate** type (peroneus longus, flexor hallucis longus, dorsal interossei). In **multipennate** muscles, there are several tendons in the muscle mass with fibers attaching obliquely from many directions, such as is seen in the deltoid muscle (Fig. 6-2).

**Triangular Muscle.** A muscle in which the fiber bundles attach to a broad tendon and converge to a more narrow apex may give, more or less, the surface appearance of a triangle. Examples of triangular type muscles include the pectoralis minor and anconeus muscles.

**Overlapping Muscle: Crossed or Spiral.** In certain muscles an overlapping course of the muscle bundles allows large numbers of fibers arising from a broad origin to converge in a laminar or twisting fashion onto the tendon(s) of insertion. Some of the bundles course in a curved direction toward the insertion, while others are straight, as is the

FIG. 6-2. Some of the morphological types of muscles.

pectoralis major muscle. A variation of this type of muscle form allows fibers arising from several sites and planes to cross, thereby becoming oriented toward the site of insertion from different directions (examples include the masseter and adductor pollicis muscles). In other muscles the fiber bundles may be arranged in a course forming, more or less, a spiral type of structure such as is seen in the supinator muscle of the forearm (Fig. 6-2).

Finally, it should be appreciated that frequently a muscle may show characteristics of several of these various muscle forms.

These arrangements of the fasciculi are correlated with the power that muscles can generate. Those with comparatively few fasciculi, extending the length of the muscle, have a greater range of motion but not much power. Penniform muscles, with a large number of fasciculi distributed along their tendons, have greater power, but a smaller range of motion, that is, their pull will be shorter but more powerful.

**NAMES OF MUSCLES.** Muscles have been named according to (1) their **location** (brachialis, pectoralis, supraspinatus); (2) their **direction** (rectus, obliquus, and transversus abdominis); (3) their **action** (flexors, extensors); (4) their **shape** (deltoid, trapezius, rhomboid); (5) the **number of divisions** (biceps, triceps, quadriceps); (6) their **points of attachment** (sternocleidomastoid, omohyoid).

**ORIGIN AND INSERTION OF MUSCLES.** The attachments of the two ends of a muscle are called the **origin** and the **insertion**, and it is customary to describe the muscle as arising from the origin and inserting at the insertion. The origin usually is the more fixed and proximal end, while the insertion is the more movable and distal end. For example, the pectoralis major arises or has its origin from the sternum, ribs, and clavicle, and its insertion is into the humerus. If the individual were climbing a tree, however, the origin and insertion would be reversed, since the upper extremity would be more fixed and the body more movable. The designations of origin and insertion in the following descriptions are, therefore, somewhat arbitrary and a matter of convention among anatomists. **Illustrations of areas of attachment** of muscles are found with the descriptions of the bones and the origins marked in red, the insertions in blue.

## Actions of Muscles

At one time muscle action was determined simply by the effect observed through manipulation of the muscle being studied in the cadaver or the deficits in muscle function seen in patients with peripheral nerve injuries. The introduction of electrical stimulation of muscles added much to our knowledge of their action, and the current use of electromyographic recordings of motor unit discharge in the muscles of human subjects is now refining our understanding and more precisely defining muscle actions.

**MOTOR UNIT.** Physiologically, a muscle contracts because a motor nerve conducts impulses to myoneural junctions where a chemical transmitter, **acetylcholine**, is released from the presynaptic nerve terminals. This transmitter apparently binds with protein molecules called **acetylcholine receptors**, found on the membrane surface of the muscle. The binding then presumably causes biophysical changes in the membrane, increasing its permeability and allowing a rapid influx of sodium ions into the muscle fiber. This initiates a postsynaptic excitation of the membranes of the somatic skeletal muscle cells.

A single motor nerve fiber innervates more than one skeletal muscle fiber. The nerve fiber and all the muscle fibers that it supplies are a functional unit, which is called the **motor unit**. In general, muscles that are small and react quickly, such as certain laryngeal and extraocular muscles, have ten or fewer muscle fibers innervated by each nerve fiber. In contrast, large muscles, such as the gastrocnemius or the deep muscles of the back, which do not require fine central nervous system control, may have as many as 500 or 1000 muscle fibers in each motor unit. Under normal resting circumstances, certain motor units in a muscle may be discharging while others are quiescent. Soon the activity of these units subsides and that of others commences, and it is this type of motor unit activity pattern that serves as the background against which muscular contraction for the performance of a purposeful act is set.

**ISOTONIC AND ISOMETRIC CONTRACTIONS.** When muscles contract, their fibers act upon certain movable structures in order to effect the desired action. Movements result from the summation of increasing numbers

of motor units in certain groups of muscles and the simultaneous relaxation of motor units in others. Movement that results from muscular contraction causes the lengths of muscles to change. Under these circumstances, the tension generated within the muscle mass remains constant and the contraction is referred to as **isotonic**. If, for some reason, movement does not occur as a result of muscular contraction, and the lengths of the muscles remain constant while the tension generated within the muscles is elevated, the contraction is said to be **isometric**. An example of isometric muscular contraction is encountered in the activities of the muscles of the calf during standing. The center of gravity would tend to allow the body to fall forward; however, this is prevented by the sustained activity of motor units in the calf muscles, causing them to contract without altering their lengths, thus, isometrically. Isotonic contractions may result in a shortening of the muscle (**concentric contraction**), or at times in its lengthening (**eccentric contraction**).

**GROUP ACTIONS OF MUSCLES.** With rare exceptions, an individual muscle does not act alone in the performance of movement. It is, however, of practical importance to understand the individual actions of muscles. For example, the surgeon who is trying to diagnose and treat a displaced part of a limb due to a fracture must depend on his knowledge of individual muscle functions to guide his decisions.

Most bodily movements require the combined action of a number of muscles. It is customary to use the term **prime mover** for those muscles that act directly to bring about the desired movement. Practically every muscle acting upon a joint is matched with another muscle that has an opposite action. Each muscle of such a pair is the **antagonist** of the other; for example, the biceps brachii, a flexor, and the triceps, an extensor, are antagonists at the elbow. An antagonist does not significantly counteract the action of a prime mover and, in fact, only shows a brief and transient discharge pattern at the initiation of movement, relaxing then until the intended action decelerates. In some instances, the antagonist actually controls the smoothness of performance. For example, if the abducted arm is allowed to lower passively to the side of the trunk, gravity serves as a substitute for the prime mover. The an-

tagonist, which is the deltoid in this instance, simultaneously lengthens, controlling the movement and retarding the force of gravity. At times prime movers and antagonists may contract together, serving to stabilize a joint or hold a part of the body in an appropriate position. Under these conditions, the muscles are said to behave as **fixators**.

Muscles that contract at the same time as prime movers are called **synergists**. The term may refer not only to muscles that potentiate the action of the prime mover, but, more meaningfully, to fixators or stabilizing muscles that contract at the same time as a prime mover, thereby preventing some unwanted movement that would be counterproductive. If antagonists contract during a given movement, even they are acting as synergists. For example, in closing the fist, the prime movers are the flexors digitorum superficialis and profundus, the flexor pollicis longus, and the small muscles of the thumb. The fixation muscles are the triceps, the biceps, the brachialis, and the muscles about the shoulder that hold the arm in position. The synergetic muscles are the extensors carpi radialis and ulnaris, which prevent flexion of the wrist. In some instances, when an act is performed with extreme force, muscles that are not required for a moderate performance come to the assistance of the prime movers. An example of this might be the flexors of the fingers, which may flex the wrist in an emergency situation.

Individual muscles cannot always be treated as single mechanical units with regard to their actions. Different parts of the same muscle may have different or even antagonistic actions. An example of this is the anterior part of the deltoid, which flexes the arm while the posterior portion extends it. Two adjacent muscles, such as the infraspinatus and the teres minor, on the other hand, may have the same action.

## Muscles and Fasciae of the Head

The muscles of the head may be arranged in groups, of which the following two will be described in this chapter:

- Facial muscles
- Muscles of mastication

In addition to these two groups, other muscles found in the head are described regionally in future chapters. These include the: (1) extraocular muscles, (2) muscles of the auditory ossicles, (3) muscles of the tongue, and (4) muscles of the pharynx.

## FACIAL MUSCLES

The **facial muscles** of expression are cutaneous muscles, lying within the layers of superficial fascia. They are derived from the mesoderm of the second pharyngeal arch and migrate to their adult locations. Generally, they arise either from fascia or from the bones of the face, and insert into the skin. The individual muscles seldom remain separate and distinct throughout their length, having a tendency to merge, especially at their sites of attachment. They may be grouped into the: (1) muscle of the scalp, (2) extrinsic muscles of the ear, (3) muscles of the eyelid, (4) muscles of the nose, (5) muscles of the mouth. An additional muscle, the platysma, really belongs to the facial group but will be described with the muscles of the neck.

### *Fasciae and Muscle of the Scalp*

Superficial fascia  
Epicranium  
Occipitofrontalis  
Temporoparietalis  
Galea aponeurotica

**SUPERFICIAL FASCIA.** The superficial fascia of the head invests the facial muscles and carries the superficial blood vessels and nerves. It varies considerably in thickness and texture in different regions, but everywhere has an abundant blood and nerve supply. Above the superior nuchal and temporal lines, and anterior to the masseter muscle, there is no deep fascia other than the periosteum of the bones. Beneath the skin of the scalp, the superficial fascia is thick and tough, and over the cranial vault, the muscular layer is replaced by the broad epicranial aponeurosis or **galea aponeurotica** (Fig. 6-3). A fascial cleft like those commonly found deep to the superficial fascia in the rest of the body is prominent in this region and separates the galea from the **pericranium** or cra-

**nial periosteum.** This cleft accounts for the movability of the scalp and makes possible the sudden accumulation of large amounts of blood that form hematomas following blows on the head. Over the forehead, the superficial layers of the fascia are much thinner than over the superior aspect of the cranial vault, and the skin is closely attached to the underlying frontal belly of the occipitofrontalis muscle. Over the eyelids, the fascia is devoid of fat and is composed of a loose areolar tissue which is easily distended and infiltrated with tissue fluid in edema, or blood in ecchymosis or hemorrhage. On the cheeks and lips, the superficial fascia contains a considerable amount of fat and is tougher and more fibrous, especially in men. In contrast, the superficial fascia is virtually absent over the cartilages of the nose and external ear, the skin being closely bound to the underlying **perichondrium**. The superficial fascia of the face is directly continuous over the mandible with that of the anterolateral neck, and that of the scalp merges posteriorly with a similar fibrous layer of the posterior neck.

The skin of the scalp is thicker than that in any other part of the body. The hair follicles are closely set together, have numerous sebaceous glands, and extend deep into the superficial fascia. The subcutaneous fat is broken into granular lobules and is matted into a firm layer by the many fibrous bands that secure the skin to the deeper layers of superficial fascia.

**THE EPICRANIUM.** The epicranium consists of the occipitofrontalis, its aponeurosis, called the galea aponeurotica, and the two thin temporoparietalis muscles. This muscular and tendinous layer covers the top and sides of the skull from the occipital bone to the eyebrow, and extends laterally as far as the squamae of the temporal bones.

The **occipitofrontalis muscle** (Fig. 6-4) consists of four thin, broad muscular bellies, two occipital and two frontal, connected by an extensive intermediate aponeurosis, the **galea aponeurotica**. The **occipital belly**, quadrilateral in form, arises by short tendinous fibers from the lateral two-thirds of the superior nuchal line of the occipital bone, and from the mastoid part of the temporal bone. The muscular fasciculi ascend in a parallel course toward the vertex and end in the galea aponeurotica. Between the muscles of the two sides of the scalp is a consider-

**Fig. 6-3.** The five layers of the scalp overlying the calvaria.

able, though variable, interval occupied by a posterior prolongation of the galea. The **frontal belly** consists of a thin quadrilateral muscular layer on each side. It is broader than the occipital belly and its fasciculi are longer, finer, and paler in color, and it has no bony attachments. Its *medial fibers* are continuous with those of the procerus; its *intermediate fibers* blend with the corrugator supercilii and orbicularis oculi; and its *lat-*

*eral fibers* are blended with the latter muscle also, over the zygomatic process of the frontal bone. The fibers are directed upward, and join the galea aponeurotica anterior to the coronal suture. The medial margins of the muscles of the two sides are joined together for some distance above the root of the nose.

The **temporoparietalis muscle** (Fig. 6-4) is a broad, thin, variable sheet of muscle on each side of the scalp. It arises from the tem-

FIG. 6-4. Superficial muscles of the face, scalp, and neck. Left lateral view.

poral fascia just above and anterior to the superior margin of the auricle of the external ear. It spreads out like a fan over the temporal fascia, and inserts into the skin and temporal fascia somewhat higher on the side of the head, nearly reaching the lateral border of the galea aponeurotica.

The **galea aponeurotica** (Figs. 6-4; 6-6), also called the **epicranial aponeurosis**, covers the upper part of the cranium between the frontal and occipital bellies of the occipitofrontalis. In addition to its attachment to these muscle bellies, its fibers extend behind, in the interval between the two occipital bellies, to the external occipital protuberance and the highest nuchal line of the

occipital bone. In front, it forms a short, narrow prolongation between the two frontal bellies. On each side it loses its aponeurotic character, and continues over the temporal fascia as a layer of laminated areolar tissue. It is closely attached to the integument by the firm, dense, adipose layer of superficial fascia and is separated more deeply from the pericranium by a fascial cleft. This allows the aponeurosis, carrying with it the integument, to move the scalp quite freely over the underlying bony calvaria.

**Action.** The occipital and frontal bellies of the **occipitofrontalis** acting together draw back the scalp, raising the eyebrows and wrinkling the fore-

head as in an expression of surprise. The frontal bellies acting alone raise the eyebrow, on one or both sides. The **temporoparietalis** tightens the scalp and draws back the skin of the temples; it combines with the occipitofrontalis to wrinkle the forehead and widen the eyes in an expression of fright or horror. The temporoparietalis raises the auricula.

**Nerves.** The frontal belly of the occipitofrontalis and the temporoparietalis are supplied by the temporal branches, and the occipital belly by the posterior auricular branch of the **facial nerve**.

**Variations.** Both frontal and occipital bellies may vary considerably in size and in extent, and either may be absent. The muscles of the two sides may fuse in the midline, and the occipital belly may fuse with the auricularis posterior muscle.

A thin muscular slip, the **transversus nuchae** or **occipitalis minor**, is present in about 25% of the bodies. It *arises* from the external occipital protuberance or from the superior nuchal line, either superficial or deep to the trapezius. Frequently, it is *inserted* with the auricularis posterior muscle, but may join the posterior edge of the sternocleidomastoid.

### Extrinsic Muscles of the Ear

Auricularis anterior  
Auricularis superior  
Auricularis posterior

**AURICULARIS ANTERIOR.** The auricularis anterior muscle is thin, pale, delicate, and indistinct. It is the smallest of the three and *arises* from the anterior portion of the fascia in the temporal area. It is fan-shaped and its fibers converge to be *inserted* into a spine on the front of the helix.

**AURICULARIS SUPERIOR.** The auricularis superior muscle is thin and fan-shaped. Its fibers *arise* from the fascia of the temporal area and converge to be *inserted* by a thin, flattened tendon into the upper part of the cranial surface of the auricula. It is the largest of the auricular muscles.

**AURICULARIS POSTERIOR.** The auricularis posterior muscle (Fig. 6-4) consists of two or three fleshy fasciculi which *arise* from the mastoid portion of the temporal bone by short aponeurotic fibers. They are *inserted* onto the medial (cranial) surface of the auricula at the convexity of the concha.

**Actions.** The **auricularis anterior** draws the auricula forward and upward; the **auricularis superior** draws it upward; and the **auricularis posterior** draws it backward. In man these muscles seem to act more in conjunction with the occipitofrontalis to move the scalp than to move the auricula, but some

individuals can use them to execute voluntary movements of the auricula.

**Nerves.** The **auriculares anterior** and **superior** are supplied by the temporal branches, and the **auricularis posterior** by the posterior auricular branch of the **facial nerve**.

### Muscles of the Eyelids

Levator palpebrae superioris  
Orbicularis oculi  
Corrugator supercilii

The **levator palpebrae superioris** is described with the anatomy of the eye.

**ORBICULARIS OCULI.** The orbicularis oculi (Figs. 6-4 to 6-6) *arises* from the nasal part of the frontal bone, from the frontal process of the maxilla in front of the lacrimal groove, and from the anterior surface and borders of a short fibrous band, the **medial palpebral ligament**. From this origin, the fibers are directed lateralward, forming a broad and thin layer which occupies the eyelids or palpebrae, surrounds the circumference of the orbit, and spreads over the temple and down the cheek. The orbicularis oculi consists of **palpebral**, **orbital**, and **lacrimal parts**.

The **palpebral part** of the muscle is thin and pale (Fig. 6-6). It *arises* from the bifurcation of the medial palpebral ligament and spreads in concentric curves over the eyelids anterior to the orbital septum. Laterally, the muscle fibers again converge to insert into the lateral palpebral raphe. A few superficial muscle fibers along the free margin of the lids behind the eyelashes are called the **ciliary bundle** (of Riolan).<sup>1</sup>

The **orbital part** is thicker and of a reddish color. Its fibers form a complete ellipse without interruption at the lateral palpebral commissure, and spread onto the forehead, temple, and cheek. The upper fibers of the orbital part blend with the frontal belly of the occipitofrontalis muscle and the corrugator supercilii. Some fibers of the orbital part insert into the skin of the eyebrow, and draw the eyebrow downward. The latter fibers constitute the **depressor supercilii**.

The **lacrimal part** is small and thin, about 6 mm in breadth and 12 mm in length, and situated behind the medial palpebral ligament and lacrimal sac (Fig. 6-5). It *arises* from the posterior crest and adjacent part of

<sup>1</sup>Jean Riolan (1577-1657): A French physician, anatomist, and botanist (Paris).

FIG. 6-5. Left orbicularis oculi, seen from behind.

the orbital surface of the lacrimal bone, and passing behind the lacrimal sac, divides into an upper and a lower slip, which are inserted into the superior and inferior tarsi medial to the puncta lacrimalia.

The **medial palpebral ligament** (Fig. 6-6), about 4 mm in length and 2 mm in breadth, is attached to the frontal process of the maxilla in front of the lacrimal groove. Crossing the lacrimal sac, it divides into upper and lower parts, each attached to the medial end of the corresponding tarsus. As the ligament crosses the lacrimal sac, it gives off from its posterior surface a strong aponeurotic lamina which expands over the sac and is attached to the posterior lacrimal crest.

The **lateral palpebral raphe** is a much weaker structure than the medial palpebral ligament. It is formed by an interlacing of the orbicularis oculi muscle fibers at the lateral angle of the eye. The raphe is attached to the margin of the frontosphenoidal process of the zygomatic bone, and passes medialward to the lateral commissure of the eyelids. Here it divides into two slips, which are attached to the margins of the respective tarsi. Deep to the raphe is the **lateral palpebral ligament**.

**CORRUGATOR SUPERCILII.** The corrugator supercilii (Figs. 6-4 to 6-6) is a small, narrow, pyramidal muscle, placed at the medial end of the eyebrow, beneath the frontal belly of the orbitofrontalis and orbicularis oculi. It arises from the medial end of the superciliary arch, and its fibers pass upward and lateralward, between the palpebral and orbital portions of the orbicularis oculi, and are inserted into the deep surface of the skin, above the middle of the orbital arch.

**Actions.** The **orbicularis oculi** is the sphincter muscle of the eyelids. The palpebral portion closes the lids gently, as in blinking or in sleep. The orbital portion is also used to close the eye, especially when a more forceful contraction is necessary, such as in winking one eye. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn toward the medial angle of the orbit, and the eyelids are firmly closed. The skin thus drawn upon is thrown into folds, especially radiating from the lateral angle of the eyelids; these folds become permanent in old age, and form the so-called "crow's feet." The levator palpebrae superioris is the direct antagonist of the orbicularis oculi, because it raises the upper eyelid and exposes the front of the bulb of the eye. Each time the eyelids are closed through the action of the orbicularis, the medial palpebral ligament is tightened, the wall of

the lacrimal sac is thus drawn lateralward and forward, and the tears are directed into the lacrimal canals. The lacrimal part of the orbicularis oculi draws the eyelids and the ends of the lacrimal canals medialward and compresses them against the surface of the globe of the eye, thus placing them in the most favorable position for receiving the tears. The **corrugator supercilii** draws the eyebrow downward and medialward, producing the vertical wrinkles of the forehead. It is the "frowning" muscle, and may be regarded as the principal muscle in the expression of suffering.

**Nerves.** These muscles are innervated by the temporal and zygomatic branches of the **facial nerve**.

### **Muscles of the Nose**

Procerus  
Nasalis  
Depressor septi

**THE PROCERUS.** The procerus muscle (Figs. 6-4; 6-6) is a small pyramidal slip arising on each side by tendinous fibers from the fascia covering the lower part of the nasal bone and upper part of the lateral nasal cartilage. Coursing superiorly over the bridge of the nose, it is inserted into the skin over the lower part of the forehead between the two eyebrows, its fibers decussating with those of the frontal belly of the occipitofrontalis muscle.

**THE NASALIS.** The nasalis muscle consists of two parts, transverse and alar. The **transverse part** (*compressor naris*) arises from the maxilla, above and lateral to the incisive fossa (Fig. 6-6). Its fibers proceed upward and medialward, expanding into a thin aponeurosis which is continuous on the bridge of the nose with that of the muscle of the opposite side, and with the aponeurosis of the procerus. The **alar part** (*dilatator naris*) arises from the maxilla above the lateral incisor tooth medial to the transverse part and is inserted into the lower part of the cartilaginous ala of the nose.

**DEPRESSOR SEPTI.** The depressor septi (Fig. 6-4) arises from the incisive fossa of the maxilla. Its fibers ascend to be inserted into the mobile part of the nasal septum. It lies between the mucous membrane and muscular structure of the lip.

**Actions.** The procerus draws down the medial angle of the eyebrows and produces transverse wrinkles over the bridge of the nose. The **transverse part of the nasalis** depresses the cartilaginous part of the nose and draws the ala toward the septum.

The **alar part of the nasalis** enlarges the aperture of the nares. Its action in ordinary breathing is to resist the tendency of the nostrils to close from atmospheric pressure, but in difficult breathing, as well as in some emotions, such as anger, it contracts strongly. The **depressor septi** draws the ala of the nose downward, and thereby constricts the aperture of the nares.

**Nerves.** These muscles are innervated by the buccal branches of the **facial nerve**.

### **Muscles of the Mouth**

Levator labii superioris  
Levator labii superioris alaeque nasi  
Levator anguli oris  
Zygomaticus minor  
Zygomaticus major  
Risorius  
Depressor labii inferioris  
Depressor anguli oris  
Mentalis  
Transversus menti  
Orbicularis oris  
Buccinator  
Pterygomandibular raphe  
Buccal fat pad

**LEVATOR LABII SUPERIORIS.** This thin quadrangular muscle (Figs. 6-4; 6-6) has a rather broad origin from the lower margin of the orbit immediately above the infraorbital foramen; some of its fibers are attached to the maxilla, others to the zygomatic bone. Its fibers converge to be inserted into the muscular substance of the upper lip between the levator anguli oris and the levator labii superioris alaeque nasi.

**LEVATOR LABII SUPERIORIS ALAEQUE NASI.** This narrow muscle (Figs. 6-4; 6-6) arises from the upper part of the frontal process of the maxilla, passes obliquely downward and lateralward, and divides into two slips. One of these is inserted into the greater alar cartilage and skin of the nose, while the other is prolonged into the upper lip, blending with the levator labii superioris.

**LEVATOR ANGULI ORIS.** This flat quadrilateral muscle (Figs. 6-4; 6-6) arises from the canine fossa, immediately below the infraorbital foramen. Its fibers are inserted into the angle of the mouth, intermingling with those of the zygomaticus major, depressor anguli oris, and orbicularis oris.

**ZYGOMATICUS MINOR.** This small bundle of muscle fibers arises from the malar surface of the zygomatic bone immediately behind the zygomaticomaxillary suture,

**FIG. 6-6.** The facial muscles, anterior view. On the right (reader's left) is shown the more superficial layer, while on the left are the deeper muscles. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban & Schwarzenberg, 11th Ed., Vol. 1, 1975.)

passes downward and medialward as a narrow slip, and is inserted into the upper lip between the levator labii superioris and the zygomaticus major (Figs. 6-4; 6-6).

**ZYGOMATICUS MAJOR.** Somewhat larger than the preceding muscle, the zygomaticus major arises from the zygomatic bone, in front of the zygomaticotemporal suture. It descends obliquely with a medial inclination to be inserted into the angle of the mouth, where it blends with the fibers of the levator and depressor anguli oris and the orbicularis oris muscle (Figs. 6-4; 6-6).

**Actions.** The levator labii superioris raises the upper lip, carrying it at the same time a little forward. The levator labii superioris alaeque nasi

raises the upper lip and also dilates the nostril. These two muscles, together with the zygomaticus minor, form the nasolabial furrow, from the side of the nose to the upper lip, which is deepened in expressions of sadness. When these three muscles act in conjunction with the levator anguli oris, the furrow is deepened into an expression of contempt or disdain. The zygomaticus major draws the angle of the mouth upward and backward in laughing.

**Nerves.** All five of the preceding muscles are supplied by buccal branches of the facial nerve.

**THE RISORIUS.** The risorius muscle (Figs. 6-4; 6-6) usually arises in the parotid fascia overlying the masseter muscle, but may arise more superiorly or posteriorly. It passes horizontally forward, superficial to the pla-

tysma, to be inserted into the skin at the angle of the mouth. The risorius varies greatly in size.

**DEPRESSOR LABII INFERIORIS.** This depressor of the lower lip is a small quadrilateral muscle that arises from the oblique line of the mandible, between the symphysis menti and the mental foramen (Figs. 6-4; 6-6). It passes upward and medialward, to be inserted into the skin of the lower lip, its fibers blending with the orbicularis oris, and with those of the depressor labii superioris of the opposite side. At its origin it is continuous with the fibers of the platysma, and considerable fat is intermingled with the fibers of this muscle.

**DEPRESSOR ANGULI ORIS.** This muscle arises from the oblique line of the mandible, lateral to and below the depressor labii inferioris. Its fibers ascend in a curved direction and are inserted as a narrow fasciculus into the angle of the mouth (Figs. 6-4; 6-6). At its origin, it is continuous with the platysma, and at its insertion, with the orbicularis oris and risorius. Some of its fibers are directly continuous with those of the levator anguli oris.

**THE MENTALIS.** The mentalis is a small conical fasciculus, situated at the side of the frenulum of the lower lip. It arises from the incisive fossa of the mandible, and descends to be inserted into the integument of the chin (Figs. 6-4; 6-6).

**TRANSVERSE MENTI.** This muscle, found in more than half the bodies, is small and crosses the midline just under the chin. It is frequently continuous with the depressor anguli oris.

**Actions.** The risorius retracts the angle of the mouth. The depressor labii inferioris draws the lower lip directly downward and a little lateralward, producing the expression of irony. The depressor anguli oris depresses the angle of the mouth, being the antagonist of the levator anguli oris and zygomaticus major; acting with the levator, it draws the angle of the mouth medialward. The mentalis raises and protrudes the lower lip, and at the same time wrinkles the skin of the chin, as in pouting or expressing doubt or disdain.

**Nerves.** These muscles of the lower lip are supplied by the mandibular and buccal branches of the facial nerve.

**ORBICULARIS ORIS.** The orbicularis oris (Figs. 6-4; 6-6) is not a simple sphincter muscle like the orbicularis oculi. It consists of

numerous strata of muscular fibers surrounding the orifice of the mouth and coursing in different directions. Some fibers of the orbicularis oris are derived from other facial muscles which insert into the lips, while other fibers are intrinsic to the muscle itself. Of the former, a considerable number are derived from the buccinator and form the deeper stratum of the orbicularis oris. Some of the buccinator fibers—namely, those near the middle of the muscle—decussate at the angle of the mouth, those arising from the maxilla pass to the lower lip, and those from the mandible to the upper lip (Fig. 6-7). The uppermost and lowermost fibers, derived from the buccinator, pass across the lips from side to side without decussation. Superficial to this stratum is a second layer, formed on each side by fibers from the levator and depressor anguli oris which cross each other at the angle of the mouth (Fig. 6-7). Those from the levator pass to the lower lip, and those from the depressor to the upper lip. Coursing along the lips, these fibers are inserted into the skin near the median line. Other muscle fibers of the orbicularis oris are derived from the levator labii superioris, the zygomaticus major, and the depressor labii inferioris. These intermingle with the transverse fibers described above, and have principally an oblique direction. The proper fibers of the lips are oblique, and pass from the undersurface of the skin to the mucous membrane through the thickness of the lip. Finally, there are fibers by which the muscle is connected with the maxillae and the septum of the nose above, and with the mandible below. In the upper lip these consist of lateral and medial bands on each side of the midline. The lateral band, called the incisivus labii superioris (Fig. 6-7), arises

Fig. 6-7. Diagram showing arrangement of fibers of orbicularis oris.

from the alveolar border of the maxilla, opposite the lateral incisor tooth, and arching lateralward, is continuous with the other muscles at the angle of the mouth. The more medial band, the **nasolabialis muscle**, connects the upper lip to the back of the septum of the nose. The interval between the two nasolabial bands corresponds to a depression, the **philtrum**, seen on the upper lip beneath the septum of the nose. Similar fibers for the lower lip constitute the **incisivus labii inferioris** on each side of the midline. This arises from the mandible, lateral to the mentalis, and intermingles with the other muscles at the angle of the mouth.

**Actions.** The **orbicularis oris**, in its ordinary action, effects the direct closure of the lips. By its deep and oblique fibers, it closely applies the lips to the teeth and the alveolar arches. The superficial part, consisting principally of the decussating fibers, brings the lips together and also protrudes them forward. Additionally, the orbicularis oris is an important muscle for speech because it alters the shape of the mouth as well as assists feeding and drinking.

**Nerves.** The orbicularis oris is supplied by the buccal branches of the **facial nerve**.

**THE BUCCINATOR.** The buccinator is the principal muscle of the cheek and forms the lateral wall of the oral cavity (Fig. 6-8). It lies deeper than the other facial muscles, is

**Fig. 6-8.** The buccinator and the muscles of the pharynx.

quadrilateral in form, and occupies the interval between the maxilla and mandible, lateral to the teeth. It arises from the outer surfaces of the alveolar processes of the maxilla above and the mandible below, opposite the three molar teeth. Posteriorly, between these two bony attachments, the buccinator also arises from the pterygo-mandibular raphe, a tendinous inscription which gives origin to the buccinator anteriorly and to the superior pharyngeal constrictor posteriorly. The fibers of the upper and lower portions follow a slightly converging course forward, and insert by blending with the deeper stratum of muscle fibers at the corresponding angle of the lips. The fibers of the central portion converge toward the angle of the mouth and decussate, those from above becoming continuous with the orbicularis oris of the lower lip, those from below with that of the upper lip.

The superficial surface of the buccinator is covered by the **buccopharyngeal fascia** and the **buccal fat pad**. Its deep surface is adjacent to the buccal glands and the mucous membrane of the mouth. The buccinator is pierced by the **duct of the parotid gland** opposite the upper second molar tooth.

**Action.** The **buccinator** compresses the cheek and is, therefore, an important accessory muscle of mastication, holding the food under the immediate pressure of the teeth. When the cheeks are distended with air, the buccinators compress them and force the air out between the lips as in blowing a trumpet (Latin: buccinator = a trumpet player). Electromyographic studies show that the orbicularis oris acts with the buccinator to compress the cheek.

**Nerve.** The motor fibers to the buccinator come from the lower buccal branches of the **facial nerve**.

**PTERYGOMANDIBULAR RAPHE.** The pterygo-mandibular raphe (Fig. 6-8) is a tendinous inscription extending superiorly from the hamulus of the medial pterygoid plate to the posterior end of the mylohyoid line of the mandible below. It gives origin to the **superior pharyngeal constrictor muscle**, which extends posteriorly from the raphe to form part of the pharyngeal wall, and the **buccinator muscle**, which courses anteriorly to form the lateral wall of the oral cavity. The medial surface of the raphe is covered by the mucous membrane of the mouth, while its lateral surface is separated from the ramus of the mandible by a quantity of adipose tissue, the **buccal fat pad**. If it were not

for the raphe, the superior pharyngeal constrictor, the buccinator, and the orbicularis oris would form a continuous sphincter-like band of muscle.

The **buccopharyngeal fascia** covers the lateral surface of the buccinator, the raphe, and the superior pharyngeal constrictor muscles. This provides a fascial cleft between the muscles and the more superficial structures overlying them, thereby allowing the muscles to move freely.

**BUCCAL FAT PAD.** This circumscribed, encapsulated mass of fat lies superficial to the buccinator at the anterior border of the masseter (Fig. 6-6). A well-defined fascial cleft separates it from the superficial fascia and facial muscles. From this main mass of adipose tissue, narrow prolongations extend deeply between the masseter and temporalis muscles and upward under the deep temporal fascia. Some of the tissue continues still more deeply into the infratemporal fossa, separating the lateral pterygoid and temporalis muscles from the maxilla, filling spaces between the various soft structures and the bony fossae. The mass superficial to the buccinator is particularly prominent in infants, and is called the **suctorial pad** because of its supposed, but dubious, assistance in the act of sucking.

## MUSCLES OF MASTICATION

The muscles of mastication directly responsible for the movements of the mandible during chewing and speech include:

- Temporalis
- Masseter
- Medial pterygoid
- Mandibular sling
- Lateral pterygoid

Overlying these muscles are the following fascial sheets:

- Temporal fascia
- Parotid-masseteric fascia
- Pterygoid fascia

**TEMPORAL FASCIA.** The temporal fascia is a strong, fibrous sheet, aponeurotic in appearance, which covers the temporalis and is used by it for the attachment of some of its fibers. It is the most cranial extension of the deep fascia, because farther cranially the deep fascia is represented only by the pericranium. It is covered by the skin and super-

ficial fascia, which includes the galea aponeurotica, the auriculares anterior and superior, and, more anteriorly, the orbicularis oculi. Just anterior to the ear, the temporal fascia is crossed by the superficial temporal vessels and auriculotemporal nerve. Superiorly, this fascia is a thin, single sheet, attached to the entire extent of the superior temporal line. More inferiorly, near its attachment to the zygomatic arch, the temporal fascia splits into two layers. The inner, or **deep layer**, ends by attaching to the medial surface of the zygomatic arch, while the outer or **superficial layer**, after attaching to the lateral border of the arch, is continued below as the masseteric fascia. Between the leaves is a small quantity of fat, the zygomatico-orbital branch of the superficial temporal artery, and a filament from the zygomaticotemporal branch of the maxillary nerve.

**PAROTID-MASSETERIC FASCIA.** The parotid-masseteric fascia covers the lateral surface of the masseter muscle and splits to enclose the parotid gland. It is attached to the zygomatic arch cranially and is continuous with the investing cervical fascia over the sternocleidomastoid posteriorly. The sheet that covers the lateral surface of the parotid gland is fused with the dense and tough overlying superficial fascia, is intimately mingled with the capsule of the gland, and sends numerous irregular septa into the glandular substance so that, unlike the submandibular gland, the parotid cannot be easily shelled from its connective tissue bed. The fascial layer on the deep surface of the gland continues behind the ramus of the mandible and there fuses with the fascia of the posterior belly of the digastric muscle into a strong band, the **stylomandibular ligament**. The fascia covering the masseter muscle, the **masseteric fascia**, terminates anteriorly by encircling the ramus of the mandible and becomes continuous with the fascia of the medial pterygoid muscle deep to the bone. The masseteric fascia is attached to the border of the mandible inferiorly and posteriorly, completing a compartment that encloses all of the muscle except its upper, deep portion, where there is a communication with the tissue spaces about the insertion of the temporalis.

**PTERYGOID FASCIA.** The pterygoid fascia invests the medial and lateral pterygoid muscles. It is continuous below, at the angle

of the mandible, with the masseteric and investing cervical fasciae, both of which become attached to the bone. In this region also, it is continuous with a thickened band, the stylomandibular ligament. The pterygoid fascia extends *upward and forward* along the deep surface of the medial pterygoid muscle to be attached with the origin of the muscle to the pterygoid process of the sphenoid bone. Inferiorly, the pterygoid fascia is attached to the mandible at both borders of the inferior half of the medial pterygoid muscle, but as this muscle angles away from the mandible toward its origin, the fascia wraps around the muscle, forming a sheet on its lateral or superficial surface. This superficial sheet, continuing upward, splits to invest the lateral pterygoid muscle, becoming attached to the skull with this muscle's origin.

The fascia between the two pterygoid muscles is attached to the skull along a line extending from the lateral pterygoid plate to the spine of the sphenoid bone. The part attached to the spine is thickened into a strong band which is attached below to the lingula of the mandible, forming the **sphenomandibular ligament**. Another band, the **pterygospinous ligament**, extends from the spine, between the two pterygoid muscles to the posterior margin of the lateral pterygoid plate. Occasionally this band is ossified, creating, between its upper border and the skull, a **pterygospinous foramen** which transmits the branches of the mandibular division of the trigeminal nerve to the muscles of mastication. Between the sphenomandibular ligament and the neck of the mandible, there is an interval that allows passage of the maxillary vessels into the infratemporal fossa.

The fascia on the lateral surface of the lateral pterygoid muscle is related to the pterygoid plexus of veins. Deep to the pterygoid and deep temporal fasciae, the layer of soft adipose tissue, which is an extension of the buccal fat pad, separates these fasciae from the buccopharyngeal fascia overlying the buccinator and superior pharyngeal constrictor muscles.

The masticator compartment contains the four muscles of mastication along with the ramus and posterior part of the body of the mandible. The compartment is enclosed laterally by the masseteric fascia and the superficial layer of the temporal fascia, and

deeply by the pterygoid and deep temporal fasciae.

**TEMPORALIS MUSCLE.** The temporalis is a broad, radiating muscle, situated at the side of the head (Fig. 6-9). It arises from the whole of the temporal fossa and from the deep surface of the temporal fascia. Its fibers converge as they descend in a tendon that passes deep to the zygomatic arch, through a space between the arch and the lateral aspect of the skull. The tendon inserts into the medial surface, apex, and anterior border of the coronoid process, and the anterior border of the ramus of the mandible nearly as far as the last molar tooth.

**Action.** The temporalis muscle elevates the mandible and thereby closes the jaws, while its posterior fibers retract the mandible.

**Nerves.** The temporalis muscle is supplied by anterior and posterior deep temporal nerves from the anterior trunk of the mandibular division of the trigeminal nerve.

**MASSETER MUSCLE.** This thick, quadrilateral muscle frequently is described as consisting of two parts, but actually consists of three—superficial, intermediate, and deep, which are superimposed and fuse anteriorly (Fig. 6-10). The **superficial part**, which is the largest, arises by a thick, tendinous aponeurosis from the zygomatic process of the max-

illa and from the anterior two-thirds of the inferior border of the zygomatic arch. Its fibers pass inferiorly and posteriorly, to be inserted into the angle and lower half of the lateral surface of the ramus of the mandible. The **intermediate part** arises from the inner surface of the anterior two-thirds of the zygomatic arch and inserts into the ramus of the mandible. The **deep part** arises from the posterior third of the inner surface of the zygomatic arch in continuity with the intermediate part. Its fibers pass anteriorly and inferiorly, to be inserted into the superior half of the ramus of the mandible, and the lateral surface of its coronoid process. The deep part of the muscle is partly concealed anteriorly by the more superficial parts, while posteriorly it is covered by the parotid gland. The fibers of the three parts blend and are continuous at their insertion.

**Action.** The masseter muscle closes the jaws by elevating the mandible.

**Nerve.** The masseter muscle is supplied by the masseteric branch of the mandibular division of the trigeminal nerve.

**MEDIAL PTERYGOID MUSCLE.** The medial pterygoid (Figs. 6-11; 6-12) is a thick, quadrilateral muscle that occupies a position on the inner aspect of the ramus of the mandible, opposite that of the masseter on the

FIG. 6-9. The temporalis muscle, lateral view with the zygomatic arch and masseter muscle removed.

**FIG. 6-10.** A lateral view of the skull showing the origin and insertion of the masseter muscle, as well as the temporalis muscle and the stylomandibular ligament. (After Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban & Schwarzenberg, 11th Ed., Vol. 1, 1975.)

outer aspect. It arises from the medial surface of the lateral pterygoid plate and the grooved surface of the pyramidal process of the palatine bone. A second, more lateral, slip of the muscle arises from the lateral surfaces of the pyramidal process of the palatine and tuberosity of the maxilla. The second slip lies superficial to the lateral pterygoid, while the main mass of the muscle lies deeper. Its fibers pass inferiorly, laterally, and posteriorly, and are inserted by a strong tendinous lamina into the lower and back part of the medial surface of the ramus and angle of the mandible, as high as the mandibular foramen. The upper portion of the muscle is separated from the mandible by the sphenomandibular ligament, the maxillary vessels, the inferior alveolar ves-

sels and nerve, and the lingual nerve. The medial surface of the muscle is closely related to the tensor veli palatini muscle and to the superior pharyngeal constrictor.

**Action.** The medial pterygoid assists in closing the jaws by elevating the mandible. The two medial pterygoids protrude the mandible, while acting with the lateral pterygoids. When one of the medial pterygoids acts with the lateral pterygoid of the same side, the mandible is protruded forward and to the opposite side. An alternation of these movements is important in the act of chewing food.

**Nerve.** The medial pterygoid branch from the mandibular division of the trigeminal nerve supplies the medial pterygoid muscle.

**MANDIBULAR SLING.** The masseter and the medial pterygoid are so placed that they sus-

pend the angle of the mandible in a muscular sling (Fig. 6-12). They form a functional articulation between the mandible and the maxilla, with the temporomandibular joint acting as a guide, in a manner similar to the articulation between the scapula and the thorax, where the clavicle acts as a guide. When the mouth is opened and closed, the mandible moves about a center of rotation established by the attachment of the sling and the sphenomandibular ligament.

**LATERAL PTERYGOID MUSCLE.** The lateral pterygoid (Figs. 6-11; 6-12) is a short, thick muscle of two heads. It is somewhat conical in form, and extends almost horizontally between the infratemporal fossa and the condyle of the mandible. The upper or **superior head** arises from the infratemporal crest and inferior part of the lateral surface of the great wing of the sphenoid bone, while the **inferior head** arises from the lateral surface of the lateral pterygoid plate. Its fibers pass horizontally backward and lateralward, to be inserted into a depression in the anterior part of the neck of the condyle of the mandible, and into the anterior margin of the articular disc of the temporomandibular joint.

**Action.** The lateral pterygoid muscle opens the mouth by drawing the condyle of the mandible and the articular disc of the temporomandibular joint forward. When the lateral pterygoids act in conjunction with the elevators of the mandible, the jaws are

protruded so that the lower incisor teeth project in front of the upper teeth. With the medial pterygoid of the same side, the lateral pterygoid protrudes the mandible, and the jaw (and chin) is rotated to the opposite side, producing a grinding movement between the upper and lower teeth.

**Nerve.** The lateral pterygoid nerve from the mandibular division of the **trigeminal nerve** supplies the lateral pterygoid muscle.

**Group Actions.** The **temporalis**, **masseter**, and **medial pterygoid** close the jaws. Biting with the incisor teeth is performed by the masseter and medial pterygoid primarily, and to some extent by the anterior portion of the temporalis. Biting or chewing with the molars calls all three into maximal action.

Opening of the jaws is performed primarily by the **lateral pterygoid** pulling forward on the condyle and rotating the mandible about the center of rotation near the angle. It is assisted, at the beginning of the action, by the mylohyoid, digastric, and geniohyoid. When the mouth is opened against great resistance, in addition to the above, the infrahyoid muscles act to fix the hyoid, and other suprahyoid muscles probably come into action. The lateral pterygoid protrudes the jaw when accompanied by appropriate synergistic action of the closing muscles. The medial pterygoid assists in protrusion of the jaw only as a synergist, along with the other closing muscles, since they prevent rotation that opens the jaws widely. If the lateral pterygoid of one side acts, the corresponding side of the mandible is drawn forward while the opposite condyle remains comparatively fixed, allowing side-to-side movements to occur, such as in the trituration of food. The mandible is retracted by the posterior fibers of the temporalis.

**FIG. 6-11.** The lateral and medial pterygoid muscles, left side, lateral view. The zygomatic arch and a portion of the ramus of the mandible have been removed, showing the position of the maxillary artery.

**FIG. 6-12.** The pterygoid and masseter muscles viewed from below, showing how the medial pterygoid and masseter form a sling suspending the angle of the mandible. (After Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban & Schwarzenberg, 11th Ed., Vol. 1, 1975.)

## Anterolateral Muscles and the Fasciae of the Neck

The **anterolateral muscles** of the neck may be arranged into the following groups:

- Superficial cervical
- Lateral cervical
- Suprahyoid
- Infrahyoid
- Triangles of the neck

- Anterior vertebral
- Lateral vertebral

The **fascial layers** of the neck will be described according to the following schema:

- Superficial cervical fascia
- Deep cervical fascia
  - Superficial investing fascia (anterior layer)
  - Pretracheal fascia (middle layer)
  - Prevertebral fascia (posterior layer)
  - Carotid sheath

## SUPERFICIAL CERVICAL FASCIA

The **superficial fascia** (Fig. 6-13) in the anterior and lateral regions of the neck is considerably thinner and less dense than the superficial fascia over the face, with which it is continuous above the border of the mandible and over the parotid gland. It has embedded in its deeper layers the fibers of the **platysma muscle**, and it is separated from the deep fascia by a distinct fascial cleft, which facilitates the action of this muscle and increases the movability of the skin in this region. It is continuous over the clavicle with the superficial fascia of the pectoral and deltoid regions. Posteriorly, it is continuous with the superficial fascia of the back of the neck which, in contrast, is thick, tough, fibrous, and tightly adherent to the deep fascia.

## DEEP CERVICAL FASCIA

The **deep cervical fascia** (Fig. 6-13) forms certain compartments and fascial clefts that are important surgically because the neck

contains structures that descend and ascend between the head and thorax, as well as structures that extend into the upper extremity.

Because descriptions of the deep cervical fascia vary throughout the literature, an understanding of the subject, at first glance, might be considered difficult. Many of these discussions are unnecessarily complex. There is, however, general agreement as to the existence of three principal layers of cervical fascia, the **investing fascia** (anterior layer), the **pretracheal fascia** (middle layer), and the **prevertebral fascia** (posterior layer) (Fig. 6-13). To these is usually added the **carotid sheath**, which contains the common carotid artery, the internal jugular vein, and the vagus nerve. Fascial layers characteristically split as they surround muscles and other organs and then fuse once again and attach firmly to adjacent bone. The layers of cervical fascia follow this pattern as they envelop the structures of the neck in their paths.

**INVESTING FASCIA** (Anterior Layer of Deep Cervical Fascia). The investing layer

**FIG. 6-13.** Cross section of the neck at the level of the seventh cervical vertebra. Observe the superficial fascia and the layers of deep cervical fascia.

attaches posteriorly on each side to the ligamentum nuchae and spinous processes of the cervical vertebrae, and coursing anteriorly, it completely encircles the neck (Figs. 6-13; 6-14). It splits to enclose two prominent superficial muscles on each side of its path, the trapezius and the sternocleidomastoid. Between these two muscles it covers the posterior triangle of the neck as a single sheet, except that it envelops the inferior belly of the omohyoid muscle as that structure crosses the posterior triangle. Extending around the neck anterior to the sternocleidomastoid muscles, the investing layer passes

in front of the strap muscles of the anterior triangle. It then extends to the midline where the corresponding halves of the two sides of this fascial layer are continuous.

Superiorly, the investing fascia fuses with the periosteum over the external occipital protuberance and the superior nuchal line of the occipital bone and the mastoid process of the temporal bone. More anteriorly, it attaches along the lower border of the body of the mandible to its angle. Between the mandibular angle and the mastoid process the fascia extends superiorly and splits to enclose the parotid gland as the **parotid fas-**

FIG. 6-14.

cia (Fig. 6-14). The layer that passes deep to the parotid is thickened between the styloid process and the angle of the mandible and is called the **stylomandibular ligament**. This sheet separates the tail of the parotid gland from the submandibular salivary gland. Anteriorly, the fascia is attached to the hyoid bone, but in the suprahyoid region the investing layer continues upward to encapsulate the submandibular gland and to attach along the length of both halves of the body of the mandible. The fascia extends inferiorly to attach to the acromion and spine of the scapula, to the clavicle, and to the manubrium sterni. Just above the manubrium and between the two sternocleidomastoids and the heads of the clavicles, the fascia remains split into two layers which attach to the anterior and posterior borders of the jugular notch. The shallow interval between the two laminae is called the **suprasternal space** (of Burns). This space contains the lower portions of the anterior jugular veins and their transverse connecting branch, the **jugular venous arch**, the sternal heads of the sternocleidomastoid muscles, and sometimes one or more lymph nodes. The anterior jugular veins, in order to reach the external jugular veins, traverse extensions of the laminated interval which are prolonged laterally, deep to the heads of the sternocleidomastoid muscles. The external and anterior jugular veins, through most of their course in the neck, appear to lie between the superficial fascia and the investing layer of deep fascia, but actually are embedded in the superficial surface of the investing sheet.

**PRETRACHEAL FASCIA** (Middle Layer of the Deep Cervical Fascia). The pretracheal fascia (Fig. 6-13) is a thin, somewhat delicate layer of connective tissue that passes across the front of the neck, anterior to the trachea and thyroid gland and deep to the strap muscles. According to some accounts, it is the epimysium of the strap muscles, but this is an inadequate description. It splits to enclose the thyroid gland and contributes to its capsule. Extending above, it attaches to and is limited superiorly by the hyoid bone. Inferiorly, it extends behind the manubrium and is continuous with the fibrous pericardium along the great vessels. Laterally, the pretracheal fascia is continuous with the anterior part of the carotid sheath, and the thyroid vessels penetrate it to supply and drain the thyroid gland.

**PREVERTEBRAL FASCIA** (Posterior Layer of the Deep Cervical Fascia). The prevertebral fascia (Fig. 6-13), similar to the investing layer, is a closely fitting fascial sheet stretching across the neck behind the esophagus and trachea and anterior to the vertebral column and the anterior vertebral muscles (longus colli, longus capitis, and others). As it extends laterally, the prevertebral fascia on each side is loosely attached to the posterior part of the carotid sheath, and it then courses beneath the sternocleidomastoid muscles. It then continues laterally around the neck to form, with the immediately overlying investing fascia, the tough fascial floor of the posterior triangle, and as such it closely invests the lateral vertebral muscles (the scalene muscles and the levator scapulae). That part of the prevertebral fascia overlying the scalene muscles is frequently and appropriately called the **scalene fascia**. Deep to the trapezius, the prevertebral fascia thins and extends posteriorly to invest the posterior vertebral muscles (splenius capitis, splenius cervicis, semispinalis capitis, and others), and finally attaches to the spines of cervical vertebrae in a manner similar to that of the investing fascial layer.

Superiorly, the prevertebral fascia reaches to the base of the skull, and inferiorly the fascia extends along the surface of the longus colli anterior to the vertebral column and into the superior mediastinum of the thorax, where it becomes continuous with the anterior longitudinal ligament. An anterior lamina of the fascia detaches in the superior mediastinum and fuses with the posterior surface of the esophagus at about the level of the sternal angle. In the posterior triangle, the roots of the brachial plexus emerge between the anterior and middle scalene muscles. As these nerves and the subclavian artery course into the axilla, they carry with them beneath the clavicle a prolongation of the prevertebral fascial layer (the "scalene fascia"), which forms the **axillary neurovascular sheath**. This prolongation is carried outward into the axilla as a sleeve around the plexus and the subclavian artery.

On the outer surface of the pharynx, anterior to the prevertebral fascia, is a filmy layer of loose areolar tissue (the epimysium of the pharyngeal constrictor muscles). Some authors have identified this as the "buccopharyngeal fascia." Last (1978), how-

ever, points out that this is not a properly developed fascial membrane and, if it were, it would serve to impede or prevent the peristaltic movements of the pharynx; thus, it clearly does not warrant the designation "fascia." Anterior to the vertebral bodies, some authors have described an additional fascial layer, the alar fascia, between the prevertebral fascia and the pretracheal fascia.

A number of important neural structures are anatomically related to the prevertebral fascia. In the posterior triangle the **spinal accessory nerve** courses along the superficial surface of the prevertebral fascia. The roots of the **cervical plexus** and **brachial plexus** arise deep to the fascia from the vertebral column, and the cervical cutaneous nerves pierce the fascia along the posterior border of the sternocleidomastoid muscle in their course to the anterior triangle. The trunks of the brachial plexus become surrounded by this same fascia as they course beneath the clavicle into the axilla. The **phrenic nerve** descends in the neck toward the thorax along the front of the anterior scalene muscle *behind the prevertebral fascia*. The **cervical sympathetic trunk** ascends in the neck along the anterior surface of the longus colli muscle, and is embedded in the prevertebral fascia.

**CAROTID SHEATH.** The carotid sheath (Fig. 6-13) is a condensation of dense connective tissue which forms a tubular investment for the common carotid artery (more superiorly, the internal carotid artery), the vagus nerve, and the internal jugular vein. The sheath is much thinner over the vein than around the other structures. The sheath is, in fact, divided into three separate compartments, one for each of its contents. It is dense around the common carotid artery and loose around the internal jugular vein. Anterolaterally, it is fused with the investing fascia, anteromedially with the pretracheal fascia, and posteriorly it attaches loosely to the prevertebral fascia. According to some authors, the carotid sheath extends superiorly as far as the base of the skull, where the internal carotid artery enters the lower end of the carotid canal. Other descriptions place its upper limit at the bifurcation of the common carotid artery. Inferiorly, the sheath reaches into the thorax as far as the brachiocephalic artery on the right and the aortic arch on the left, from which the common carotid arteries

are derived, and it is often described as the upward continuation of the fibrous pericardium, indeed, a form of tunica externa for the common carotid artery.

## SUPERFICIAL CERVICAL MUSCLE

**THE PLATYSMA.** The platysma (Figs. 6-4; 6-6) is a broad sheet of muscle arising in the superficial fascia covering the superior parts of the pectoralis major and deltoid muscles. Its fibers ascend over the clavicle, and proceed obliquely upward and medialward along the side of the neck. The most anterior fibers interlace across the midline, inferior and posterior to the symphysis menti, with those of the muscle of the opposite side. The posterior fibers cross the border of the mandible superficial to the facial vessels, and some are inserted into the mandible below the oblique line, while others insert into the skin and subcutaneous tissue of the lower part of the face. Many of these latter fibers blend with the muscles about the angle and lower part of the mouth. Under cover of the platysma, the external jugular vein descends from the angle of the mandible to the clavicle. The platysma may be composed of delicate, pale, scattered fasciculi, or may form a broad layer of robust dark fibers. It may be deficient or reach well below the clavicle, and it may extend into the face for a short distance or may continue as high as the zygoma. An additional band, the **occipitalis minor**, may join the platysma from the superficial fascia over the occipital bone and mastoid process to the fascia over the insertion of the sternocleidomastoid muscle.

**Action.** The platysma muscle draws the lower lip and corner of the mouth laterally and inferiorly, partially opening the mouth, as in an expression of surprise or horror. When all the fibers act maximally, the skin over the clavicle is wrinkled and drawn toward the mandible, increasing the diameter of the neck, such as is seen during the intensive respiration of a sprinting runner. Electromyography has shown that it is not used in laughing or in motions of the jaw or the head.

**Nerve.** The platysma is supplied by the cervical branch of the facial nerve.

## LATERAL CERVICAL MUSCLES

Trapezius  
Sternocleidomastoid

The **trapezius** muscle is described with the muscles connecting the upper limb to the vertebral column.

**THE STERNOCLEIDOMASTOID.** The sternocleidomastoid muscle (Fig. 6-15) passes obliquely across the side of the neck, dividing the cervical region on each side into two triangular areas, the anterior and posterior triangles of the neck. The **anterior triangle** is bounded by the midline *anteriorly*, the medial border of the sternocleidomastoid *laterally*, and the body of the mandible *superiorly*. The **posterior triangle** is bounded by the clavicle *inferiorly*, and by the interfacing posterior border of the sternocleidomastoid *anteriorly*, and the anterior border of the trapezius *posteriorly*.

The sternocleidomastoid is thick and narrow at its central part, but is broad and thin at each end. It arises below from the sternum and clavicle by two heads. The **medial** or **sternal head** is rounded and tendinous ventrally, but fleshy dorsally, and it arises from the upper part of the ventral surface of the manubrium sterni, being directed upward and dorsally. The **lateral** or **clavicular head**, composed of fleshy and aponeurotic fibers, arises from the superior border and anterior surface of the medial third of the clavicle. It is directed almost vertically upward. The two heads are separated at their origins by a triangular interval, but gradually blend below the middle of the neck, so that the clavicular head passes behind the sternal head. These form a thick, rounded muscle which is inserted by a strong tendon into the lateral surface of the mastoid process, from its apex to its superior border, and by a thin aponeurosis into the lateral half of the superior nuchal line of the occipital bone.

**Action.** The sternocleidomastoid muscle of one side bends the head laterally, approximating the ear toward the shoulder of the same side. At the same time it rotates the head, directing the face upward and to the opposite side. The anterior fibers of both muscles acting together flex the head, bringing it ventrally, whereas the posterior fibers extend the head since they insert behind the atlanto-occipital joint (Last, 1954). If the head is fixed, the two muscles assist in elevating the thorax during forced inspiration.

**Nerves.** The sternocleidomastoid is supplied by the spinal part of the **accessory nerve** and branches from the anterior rami of the **second and third cervical nerves**.

**Variations.** The sternocleidomastoid varies in the extent of its origin from the clavicle: in some cases the clavicular head may be as narrow as the sternal; in others it may be as much as 7.5 cm in breadth. When the clavicular origin is broad, it is occasionally subdivided into several slips, separated by narrow intervals. More rarely, the adjoining margins of the sternocleidomastoideus and trapezius have been found in contact.

The **supraclavicularis** is a relatively rare anomalous muscle which extends from the upper edge of the manubrium laterally to about the middle of the clavicle along its upper surface.

## SUPRAHYOID MUSCLES

Digastric  
Stylohyoid  
Stylohyoid ligament  
Mylohyoid  
Geniohyoid

**DIGASTRIC MUSCLE.** The digastric muscle (Fig. 6-15) consists of two fleshy bellies united by an intermediate rounded tendon. It lies below the body of the mandible, and extends, in a curved form, from the mastoid process to the symphysis menti. The **posterior belly**, longer than the anterior, arises from the mastoid notch of the temporal bone and passes anteriorly and inferiorly. The **anterior belly** arises from a depression on the inner side of the inferior border of the mandible, close to the symphysis, and passes posteriorly and inferiorly. The two bellies end in an intermediate tendon which perforates the stylohyoid muscle, and which is connected to the side of the body and greater horn of the hyoid bone by a fibrous loop, which is sometimes lined by a synovial sheath. A broad aponeurotic layer, called the **suprahyoid aponeurosis**, extends from the tendon of the digastric and attaches to the body and greater horn of the hyoid bone.

**Action.** The digastric muscle elevates the hyoid bone, and the two digastric muscles acting together assist the lateral pterygoid muscles in opening the mouth by depressing the mandible.

**Nerves.** The anterior belly of the digastric is supplied by the mylohyoid nerve from the inferior alveolar branch of the mandibular division of the **trigeminal nerve**. The posterior belly is supplied by a branch of the **facial nerve**.

The two bellies are innervated by different nerves because they are derived from the mesenchyme of different branchial arches; the anterior belly forms

FIG. 6-15. Muscles of the neck. Lateral view.

from the first or **mandibular arch**, and the posterior belly from the second or **hyoid arch**.

**Variations.** The posterior belly may arise partly or entirely from the styloid process, or be connected by a slip to the middle or inferior constrictor. The anterior belly may be doubled, or extra slips from this belly may pass to the jaw or mylohyoid, or decussate with a similar slip on the opposite side. The anterior belly may be absent and the posterior belly inserted into the middle of the jaw or hyoid bone. The intermediate tendon between the two bellies may pass in front of or, more rarely, behind the stylohyoid.

At times an anomalous muscle, the **mentohyoid**, passes from the body of the hyoid bone to the chin.

**STYLOHYOID MUSCLE.** The stylohyoid (Fig. 6-15) is a slender muscle lying anterior and superior to the posterior belly of the digastric. It arises by a small tendon from the posterior and lateral surface of the styloid process near its base. Passing anteriorly and inferiorly, the stylohyoid is inserted into the body of the hyoid bone at its junction with the greater horn and just above the omohyoid. It is perforated, near its insertion, by the tendon of the digastric.

**Action.** The stylohyoid elevates and retracts the hyoid bone, thereby elongating the floor of the mouth.

**Nerve.** The stylohyoid is supplied by a branch of the **facial nerve**.

**Variations.** Occasionally the stylohyoid may be absent or doubled, or it may lie beneath the carotid artery, or be inserted into the omohyoid, thyrohyoid, or mylohyoid.

**STYLOHYOID LIGAMENT.** The stylohyoid ligament is a fibrous cord that attaches to the tip of the styloid process of the temporal bone above, and to the lesser horn of the hyoid bone below. In its course it gives origin to some fibers of the middle pharyngeal constrictor and its lower portion lies deep to the hyoglossus muscle. It represents an unossified part of the skeleton of the second pharyngeal arch, frequently containing a little cartilage in its center. The ligament may be partially ossified, and in many animals it forms a distinct bone, the **epihyal**.

**MYLOHYOID MUSCLE.** The mylohyoid is a flat, triangular muscle located immediately superior to the anterior belly of the digastric, and forms, with its fellow of the opposite

side, the muscular floor of the oral cavity. It arises from the entire length of the mylohyoid line of the mandible, extending from the symphysis menti to the last molar tooth. The **posterior fibers** pass medially and slightly downward, to be inserted into the body of the hyoid bone. The **middle** and **anterior fibers** are inserted into a median fibrous raphe extending from the symphysis menti to the hyoid bone, where they join at an angle with the fibers of the opposite muscle. This median raphe is sometimes wanting, and then the fibers of the two muscles are continuous.

**Action.** The **mylohyoid muscles** raise the floor of the mouth during swallowing. They elevate the hyoid bone, thereby pushing the tongue upward as in swallowing or protrusion of the tongue (Whillis, 1946). Additionally, the mylohyoids may depress the mandible and, therefore, assist in opening the mouth. Thus, they are active in mastication, deglutition, sucking and blowing (Lehr et al., 1971).

**Nerve.** The mylohyoid is supplied by the mylohyoid branch of the inferior alveolar nerve. The latter nerve is derived from the mandibular division of the **trigeminal nerve**.

**Variations.** At times the mylohyoid muscle may be fused with the anterior belly of the digastric, and accessory slips of the mylohyoid to other hyoid muscles are frequent.

**GENIOHYOID MUSCLE.** The geniohyoid is a narrow muscle, situated above the medial border of the mylohyoid. (Note: In dissection from the cervical approach, the geniohyoid lies deep to the mylohyoid.) It arises from the inferior mental spine on the inner surface of the symphysis menti, and runs posteriorly and slightly inferiorly, to be inserted into the anterior surface of the body of the hyoid bone. It lies in contact with its fellow of the opposite side.

**Action.** The **geniohyoid muscles** slightly elevate and draw the hyoid bone forward, shortening the floor of the oral cavity for the reception of food during feeding. If the hyoid bone remains fixed, the geniohyoids help to retract and depress the mandible.

**Nerve.** The geniohyoid is supplied by fibers of the **first cervical nerve**, that are carried along the hypoglossal nerve.

**Variations.** At times the muscle fibers of the two geniohyoids actually fuse. Muscular slips from the geniohyoid to the greater horn of the hyoid bone and the hyoglossus also occur.

**Group Actions.** The **suprahyoid muscles** perform two very important actions. During deglutition they raise the hyoid bone. When the hyoid bone is fixed by its depressors, the **infrahyoid muscles**, the suprahyoid muscles assist in opening the mouth by depressing the mandible.

## INFRAHYOID MUSCLES

Sternohyoid  
Sternothyroid  
Thyrohyoid  
Omohyoid

**STERNOHYOID MUSCLE.** The sternohyoid (Figs. 6-15; 6-16) is a thin, narrow strap muscle which arises from the posterior surface of the medial end of the clavicle, the posterior sternoclavicular ligament, and the upper and back part of the manubrium sterni. Passing superiorly and medially, it is inserted by short, tendinous fibers into the lower border of the body of the hyoid bone. The two sternohyoids are separated inferiorly by a considerable interval, but their medial borders come into contact about midway along their course, thereafter remaining contiguous above until their insertions. The sternohyoid sometimes presents a transverse tendinous inscription immediately above its origin.

**Action.** The **sternohyoid** depresses the hyoid bone after a bolus of food has been swallowed. It also acts importantly as an antagonist of the elevators of the hyoid bone and larynx.

**Nerve.** The sternohyoid is supplied by a branch of the **ansa cervicalis**, containing fibers from the **first, second, and third cervical nerves**.

**Variations.** The muscle may be absent or duplicated on one or both sides, or an additional muscular slip, the **cleidohyoid muscle**, may be present extending from the clavicle to the hyoid.

**STERNOTHYROID MUSCLE.** The sternothyroid (Fig. 6-16) is shorter and wider than the sternohyoid and is situated immediately deep to it in the neck. It arises from the posterior surface of the manubrium sterni, below the origin of the sternohyoid, and from the edge of the cartilage of the first rib, and sometimes that of the second rib. It ascends to be inserted into the oblique line on the lamina of the thyroid cartilage. The two sternothyroids are in close contact in the

**Fig. 6-16.** Muscles of the neck. Anterior view. On the right side certain of the more superficial muscles have been removed.

lower part of the neck, but diverge somewhat as they ascend. Occasionally the sternothyroid is crossed by a transverse or oblique tendinous inscription.

**Action.** The **sternothyroid** draws the larynx downward after it has been elevated during deglutition.

**Nerve.** The sternothyroid is supplied by a branch of the ansa cervicalis, containing fibers from the **first three cervical nerves**.

**Variations.** The sternothyroid may occasionally be absent or duplicated. It also may send accessory slips to the thyrohyoid, inferior pharyngeal constrictor, or the carotid sheath.

**THYROHYOID MUSCLE.** The thyrohyoid (Figs. 6-15; 6-16) is a small, quadrilateral muscle which appears to be an upward continuation of the sternothyroid. It arises from the oblique line on the lamina of the thyroid cartilage, and is inserted into the inferior border of the greater horn of the hyoid bone.

**Action.** The **thyrohyoid** depresses the hyoid bone or, if the latter is fixed, draws the thyroid cartilage superiorly.

**Nerve.** The thyrohyoid is supplied by fibers

from the **first cervical nerve**, which course with the hypoglossal nerve and branch from it before the superior root of the ansa cervicalis descends from the hypoglossal.

**OMOHYOID MUSCLE.** The omohyoid (Figs. 6-15; 6-16) consists of two fleshy bellies united by a central tendon. It arises from the upper border of the scapula, and occasionally from the superior transverse ligament which crosses the scapular notch. Its extent of attachment to the scapula varies from a few millimeters to 2.5 cm. From this origin, the **inferior belly** forms a flat, narrow fasciculus, which inclines forward and slightly upward across the lower part of the neck, being attached to the clavicle by a fibrous expansion. It then passes deep to the sternocleidomastoid, ending in its intermediate tendon. Forming an obtuse angle with the inferior belly, the **superior belly** passes almost vertically upward from the tendon, close to the lateral border of the sternohyoid, to be inserted into the lower border of the body of the hyoid bone, lateral to the insertion of the sternohyoid. The central tendon of this muscle varies somewhat in length and

form. It is held in position at the level of the cricoid cartilage by a process of the superficial investing layer of the deep cervical fascia, which sheathes it, and is prolonged caudally to be attached to the clavicle and first rib. It is by this fascial attachment that the angular form of the muscle is maintained.

**Action.** The omohyoid helps to depress the hyoid bone after it has been elevated.

**Nerves.** Both bellies of the omohyoid are supplied by branches from the ansa cervicalis, containing fibers from the first, second, and third cervical nerves.

**Group Actions.** The infrahyoid muscles depress the larynx and hyoid after these structures have been elevated with the pharynx in the act of deglutition. The omohyoids not only depress the hyoid bone, but carry it dorsalward and to one or the other side. These latter muscles are concerned especially in prolonged inspiratory efforts because they render the lower part of the cervical fascia tense, thereby lessening the inward suction of the soft parts which would otherwise compress the great vessels and the apices of the lungs.

### Triangles of the Neck

The cervical region is divided by the sternocleidomastoid muscle into an anterior and a posterior triangle.

The **anterior triangle of the neck** is bounded by the anterior midline, the anterior border of the sternocleidomastoid, and the lower border of the mandible. This triangle is further subdivided into three triangles.

1. The **submandibular triangle**, found above the hyoid bone, is bounded superiorly by the inferior border of the mandible, inferiorly by the posterior belly of the digastric, and anteriorly by the anterior belly of the digastric.

2. The **carotid triangle**, located both above and below the hyoid bone, is bounded superiorly by the posterior belly of the digastric, posteriorly by the anterior border of the sternocleidomastoid, and inferiorly by the superior belly of the omohyoid.

3. The **muscular triangle**, located below the hyoid bone, is bounded superiorly by the superior belly of the omohyoid, inferiorly by the anterior border of the sternocleidomastoid muscle, and medially by the anterior midline of the neck.

The **posterior triangle of the neck** is bounded below by the middle third of the clavicle and by the interfacing borders of the trapezius and sternocleidomastoid muscles. It is further subdivided by the inferior belly of the omohyoid into two triangles.

1. The **occipital triangle**, found above, is bounded inferiorly by the inferior belly of the omohyoid, anteriorly by the posterior border of the sternocleidomastoid muscle, and posteriorly by the anterior border of the trapezius.

2. The **omoclavicular** (subclavian or supraclavicular) **triangle**, located below, is bounded superiorly by the inferior belly of the omohyoid, anteriorly by the sternocleidomastoid muscle, and inferiorly by the clavicle.

Finally, the area between the right and left anterior bellies of the digastric muscles and the body of the hyoid bone forms the **submental triangle**, which is unpaired.

### ANTERIOR VERTEBRAL MUSCLES

Longus colli  
Longus capitis  
Rectus capitis anterior  
Rectus capitis lateralis

**LONGUS COLLI MUSCLE.** The longus colli is situated along the anterior surface of the vertebral column, between the atlas and the third thoracic vertebra (Fig. 6-17). It is broad in the middle, narrow and more pointed at each end, and consists of three portions: a superior oblique, an inferior oblique, and a vertical portion. The **superior oblique portion** arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebrae. It ascends obliquely with a medial inclination and is inserted by a narrow tendon into the tubercle on the anterior arch of the atlas. The **inferior oblique portion**, the smallest part of the muscle, arises from the anterior surface of the bodies of the first two or three thoracic vertebrae and, ascending obliquely in a lateral direction, is inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebrae. The **vertical portion**, interposed between the other two parts, arises from the anterolateral surface of the bodies of the first three thoracic and last three cervical vertebrae, and is inserted into

the anterior surface of the bodies of the second, third, and fourth cervical vertebrae.

**Action.** The longus colli is a rather weak flexor of the neck. It also slightly rotates and laterally bends the cervical portion of the vertebral column.

**Nerves.** The longus colli is supplied by branches from ventral rami of the second to the sixth cervical nerves.

**LONGUS CAPITIS MUSCLE.** The longus capitis (Fig. 6-17) is narrow below but becomes broader and thicker above. It arises by four tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebrae, and ascends, converging medially toward the opposite longus capitis, to be inserted into the inferior surface of the basilar part of the occipital bone, lateral to the pharyngeal tubercle.

**Action.** The longus capitis flexes the head and the upper cervical spine.

**Nerves.** The longus capitis is supplied by branches from the first, second, and third cervical nerves.

**RECTUS CAPITIS ANTERIOR MUSCLE.** This short, flat muscle is situated immediately deep to the superior part of the longus capitis (Fig. 6-17). It arises from the anterior surface of the lateral mass of the atlas, and from the root of its transverse process. It passes upward and slightly medially, to be inserted into the inferior surface of the basilar part of the occipital bone immediately anterior to the foramen magnum. It can be considered an upward continuation of the anterior intertransverse muscles seen between lower cervical vertebrae.

**Action.** The rectus capitis anterior flexes the head and helps to stabilize the atlanto-occipital joint.

**Nerve.** This muscle is supplied by fibers from the anterior rami of the first (and possibly the second) cervical nerve.

FIG. 6-17. The anterior and lateral vertebral muscles.

**RECTUS CAPITIS LATERALIS MUSCLE.** The rectus capitis lateralis is also a short, flat strap muscle (Fig. 6-17). It arises from the superior surface of the transverse process of the atlas, and is inserted into the inferior surface of the jugular process of the occipital bone. This muscle is comparable to the posterior cervical intertransverse muscle.

**Action.** The rectus capitis lateralis bends the head laterally to the same side and assists in stabilizing the atlanto-occipital joint.

**Nerve.** The rectus capitis lateralis, similar to the anterior, is supplied by a branch of the loop between the first and second cervical nerves.

**Group Actions.** The longus capitis and rectus capitis anterior are the direct antagonists of the muscles at the back of the neck and restore the head to its natural position after it has been drawn backward. These muscles also flex the head, and due to their obliquity, rotate it, turning the face to one or the other side. The rectus capitis lateralis, acting on one side, bends the head laterally. The longus colli flexes and slightly rotates the cervical portion of the vertebral column.

## LATERAL VERTEBRAL MUSCLES

Scalenus anterior  
Scalenus medius  
Scalenus posterior

### SCALENUS ANTERIOR MUSCLE.

anterior (Fig. 6-17) lies at the side of the neck, deep to the sternocleidomastoid muscle. It arises by four slender tendons, one each from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebrae. Descending almost vertically, it is inserted by a narrow, flat tendon onto the scalene tubercle on the inner border of the first rib, and into the ridge on the upper surface of the rib anterior to the groove for the subclavian artery.

**Action.** If the neck is fixed, the scalenus anterior elevates the first rib as an accessory muscle of respiration. If the first rib is fixed, this muscle bends the neck forward and laterally, and rotates it to the opposite side.

**Nerves.** The scalenus anterior is innervated by branches from the anterior rami of the fifth and sixth (and sometimes the fourth) cervical nerves.

### SCALENUS MEDIUS MUSCLE.

medius (Fig. 6-17) is the largest and longest

of the three scalene muscles. It arises from the posterior tubercles of the transverse processes of the last six cervical vertebrae, and from the atlas as well in over 50% of the cases. Descending along the side of the vertebral column, it is inserted by a broad attachment into the cranial surface of the first rib, between the tubercle and the groove for the subclavian artery.

**Action.** The scalenus medius, similar to the scalenus anterior, raises the first rib from above, or bends and slightly rotates the neck from below.

**Nerves.** The scalenus medius is supplied by branches from anterior rami of the third through the eighth cervical nerves.

### SCALENUS POSTERIOR MUSCLE.

smallest and most deeply seated of the three scalene muscles (Fig. 6-17). It arises by separate tendons from the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebrae, and is inserted by a thin tendon into the outer surface of the second rib, deep to the attachment of the serratus anterior. It is occasionally blended with the scalenus medius.

**Action.** The scalenus posterior raises the second rib or bends and slightly rotates the neck.

**Nerves.** The scalenus posterior is supplied by branches of ventral primary divisions of the last three cervical nerves.

**Group Actions.** When the scalenes are fixed superiorly, they elevate the first and second ribs and are, therefore, inspiratory muscles. Acting from below, they bend the vertebral column to the same side. If the muscles of both sides act, the vertebral column is flexed slightly.

**Variations.** The scalene muscles vary considerably in their attachments and in the arrangement of their fibers. A slip from the scalenus anterior may pass behind the subclavian artery. The scalenus posterior may be absent or extend to the third rib.

The scalenus pleuralis muscle or scalenus minimus extends from the transverse process of the seventh cervical vertebra to the fascia supporting the dome of the pleura and inner border of the first rib.

## Fasciae and Muscles of the Trunk

The muscles of the trunk may be arranged in six groups:

Deep muscles of the back  
Suboccipital muscles

Muscles of the thorax  
 Muscles of the abdomen  
 Muscles of the pelvis  
 Muscles of the perineum

### DEEP MUSCLES OF THE BACK

The deep or intrinsic muscles of the back consist of a complex, serially arranged group of muscles that extends from the pelvis to the skull. They may be divided into four subgroups: the **splenius**, the **erector spinae**, the **transversospinalis**, and the **interspinal-intertransverse**.

The **splenius group** (Fig. 6-20) is situated on the posterior aspect of the neck and upper thorax, and extends and rotates the head and neck. The two muscles are the:

Splenius capitis muscle  
 Splenius cervicis muscle

The **erector spinae** (sacrospinalis) is a great mass of muscle that stretches from the sacrum to the skull (Fig. 6-19). This mass splits in the upper lumbar region into lateral, intermediate, and medial columns of muscles that lie parallel. These columns are further subdivided into three muscles according to the vertebral region to which each attaches superiorly. Muscles comprising the erector spinae primarily extend and laterally bend the vertebral column. They are the:

Iliocostalis muscle (lateral column)  
   Iliocostalis lumborum  
   Iliocostalis thoracis  
   Iliocostalis cervicis  
 Longissimus muscle (intermediate column)  
   Longissimus thoracis  
   Longissimus cervicis  
   Longissimus capitis  
 Spinalis muscle (medial column)  
   Spinalis thoracis  
   Spinalis cervicis  
   Spinalis capitis

The **transversospinalis group** (Figs. 6-19; 6-20) is so named because generally the fibers of these muscles extend from the transverse processes of vertebrae upward and medially to the spinous processes of higher vertebrae. In this group are the:

Semispinalis muscle  
   Semispinalis thoracis

Semispinalis cervicis  
 Semispinalis capitis  
 Multifidus muscles  
 Rotatores muscles  
   Rotatores thoracis  
   Rotatores cervicis  
   Rotatores lumborum

The **interspinal-intertransverse group** (Fig. 6-20) includes those muscles that pass from the spinous process of one vertebra to the spine of the next vertebra, or the transverse process of one vertebra to the transverse process of the next vertebra. In this group are the:

Interspinalis muscles  
   Interspinalis cervicis  
   Interspinalis thoracis  
   Interspinalis lumborum  
 Intertransversarii muscles  
   Intertransversarii anterior cervicis  
   Intertransversarii posterior cervicis  
     Medial and Lateral  
   Intertransversarii thoracis  
   Intertransversarii lumborum  
     Medial and Lateral

Overlying these muscles is an extensive layer of deep fascia. Although the deep fascia covering cervical, thoracic, and lumbar structures can be considered as a continuous layer, two portions of it will be described separately. These are the:

Nuchal fascia  
 Thoracolumbar fascia

**NUCHAL FASCIA.** The nuchal fascia is the cervical portion of the more extensive deep fascia of the back, and it is continuous on each side of the neck with the prevertebral layer of cervical fascia covering the scalene muscles (the **scalene fascia**). It covers the splenius capitis and splenius cervicis muscles and, near the skull, the upper portion of the semispinalis capitis. With these muscles, it is attached to the skull just inferior to the superior nuchal line. Medially, it fuses with the ligamentum nuchae and the spinous processes of the seventh cervical and first six thoracic vertebrae. In the cranial part of the neck it is more or less adherent to the superficial investing layer of cervical fascia on the deep surface of the trapezius. More caudally, a distinct fascial cleft separates it from the fascia of the serratus posterior superior and rhomboid muscles.

The deep muscles of the neck are enclosed by fascial septa which form compartments for each muscle. A fascial cleft separates the splenius capitis and splenius cervicis from the semispinalis capitis. A considerable layer of adipose tissue and a fascial cleft intervene between the semispinalis capitis and semispinalis cervicis. In this adipose layer are found the deep cervical blood vessels. The fascia covering the semispinalis cervicis continues superiorly from the atlas to form the thick adherent covering of the suboccipital muscles.

**THORACOLUMBAR FASCIA.** The thoracolumbar or lumbodorsal fascia (Figs. 6-18; 6-29; 6-42), in general terms, is the deep fascial complex that forms the sheath of the erector spinae muscle. In the **thoracic region** this fascial layer is thin, gray, and transparent, attaching medially to spines of the vertebrae and the supraspinal ligaments, and laterally, at the margin of the erector spinae, to the angles of the ribs and to the fascia covering

the intercostal muscles. Becoming thinner as it ascends in the thorax, the fascia continues superiorly, deep to the rhomboids, and gradually fades out above the first rib.

In the **lumbar region**, the thoracolumbar fascia is considerably thickened and encases the erector spinae by its **posterior** and **anterior** layers. Medially, the white glistening posterior layer, which covers the dorsal surface of the erector spinae, attaches to the spinous processes of the lumbar and sacral vertebrae. The anterior layer, which stretches between the ventral surface of the erector spinae and the quadratus lumborum, attaches to the transverse processes of the lumbar vertebrae. Extending laterally from these bony attachments, the two laminae blend with the aponeuroses of the latissimus dorsi, the internal oblique, and the transversus abdominis muscles. The aponeurosis of the latissimus dorsi blends with the posterior layer, while the aponeuroses of the internal oblique and transversus abdominis

**FIG. 6-18.** Cross section through the posterior abdominal wall, showing the posterior and anterior layers of the thoracolumbar fascia along with the investing transversalis fascia. (After Sobotta.)

blend with the anterior layer. Inferiorly, the layers attach not only to the medial crest of the sacrum, but also to the lateral sacral crests, the iliolumbar ligaments, and the iliac crests. Superiorly, the posterior layer extends over the thorax, as described above, while the anterior layer extends to the twelfth rib and attaches to it and to the transverse processes of the first two lumbar vertebrae as the **lumbocostal ligament**.

A third fascial layer usually discussed in relation to the thoracolumbar fascia covers the anterior surface of the quadratus lumborum muscle. It is the thinnest of the layers in the lumbar region and is attached medially to the anterior surfaces of the transverse processes of the lumbar vertebrae posterior to the lateral part of the psoas major muscle. Some authors describe this layer as a continuation of the **fascia transversalis** extending over the inner aspect of the posterior abdominal muscles, while others describe this layer as joining laterally with the aponeurosis of the transversus abdominis muscle in conjunction with the fascial layer covering the anterior surface of the erector spinae. In the latter schema the lumbodorsal fascia is described as consisting of posterior (dorsal to erector spinae), middle (ventral to the erector spinae), and anterior (ventral to the quadratus lumborum) layers. The former schema (used in this book) calls the two layers in contact with the erector spinae the anterior and posterior layers of the lumbodorsal fascia and recognizes the fascia ventral to the quadratus lumborum as a continuation of the fascia transversalis.

### **Splenius Muscle Group**

**SPLЕНИUS CAPITIS.** The splenius capitis muscle (Fig. 6-20) is a flat muscle arising from the caudal half of the ligamentum nuchae, the spinous process of the seventh cervical vertebra, and the spinous processes of the first three or four thoracic vertebrae. The fibers of the muscle are directed upward and laterally and inserted into the rough surface on the occipital bone just inferior to the lateral third of the superior nuchal line and, under cover of the sternocleidomastoid, into the mastoid process of the temporal bone.

**Action.** The **splenius capitis** draws the head dorsally and laterally and so rotates the head, turn-

ing the face to the same side. When both splenius capitis muscles act together, they extend the head.

**Nerves.** The splenius capitis is supplied by lateral branches of the dorsal rami of the **middle cervical nerves**.

**SPLЕНИUS CERVICIS.** The splenius cervicis (Fig. 6-20) is a narrow band of muscle that arises from the spinous processes of the third to the sixth thoracic vertebrae. Ascending in the posterior neck, it is inserted by tendinous fasciculi into the posterior tubercles of the transverse processes of the upper two or three cervical vertebrae.

**Action.** The **splenius cervicis** draws the neck dorsally and laterally and also rotates the cervical vertebrae, thereby assisting to turn the head to the same side. Acting together, the two splenius cervicis muscles extend and arch the neck.

**Nerves.** The splenius cervicis is innervated by lateral branches of the dorsal primary divisions of the **lower cervical nerves**.

**Variations.** Accessory slips of the splenius muscles are frequently found, especially one that attaches to the first cervical vertebra, the atlas.

### **Erector Spinae (Sacrospinalis)**

The **erector spinae** muscle (Fig. 6-19) and its prolongations in the thoracic and cervical regions lie in the groove on the side of the vertebral column. They are covered in the lumbar and thoracic regions by the thoracolumbar fascia, and in the cervical region by the nuchal fascia, over which are found the splenius and serratus posterior superior muscles above and the serratus posterior inferior muscle below. This large muscular and tendinous mass varies in size and structure at different parts of the vertebral column. In the sacral region it is narrow and pointed, and at its origin below chiefly tendinous. In the lumbar region it is larger, and forms a thick fleshy mass which, in its ascending course, is subdivided into three vertical columns. These gradually diminish in mass as parts of the muscle insert successively into the vertebrae and ribs.

The erector spinae arises from the anterior surface of a broad and thick tendon, which is attached to the median sacral crest, to the spinous processes of the lumbar and lower two thoracic vertebrae and their supraspinal ligaments, to the inner aspect of

FIG. 6-19. Deep muscles of the back. The erector spinae.

the dorsal part of the iliac crests, and to the lateral crests of the sacrum, where it blends with the sacrotuberous and posterior sacroiliac ligaments. Some of its fibers are continuous with the fibers of origin of the gluteus maximus. The muscular fibers form a large fleshy mass which splits, in the upper lumbar region, into three columns: a *lateral*, the **iliocostalis**; an *intermediate*, the **longissimus**; and a *medial*, the **spinalis**. Each of these columns consists of three parts (Fig. 6-19).

Iliocostalis (lateral column)  
     Iliocostalis lumborum  
     Iliocostalis thoracis  
     Iliocostalis cervicis

The iliocostalis column is a substantial mass of muscle that ascends as the most laterally oriented portion of the erector spinae.

**ILIOCOSTALIS LUMBORUM.** The iliocostalis lumborum (Fig. 6-19) splits from the erector spinae mass at the upper lumbar level and ascends to be inserted by six or seven flattened tendons into the inferior borders of the angles of the last six or seven ribs.

**ILIOCOSTALIS THORACIS.** The iliocostalis thoracis (Fig. 6-19) arises by flattened tendons from the upper borders of the angles of the lower six ribs medial to the tendons of insertion of the iliocostalis lumborum. These become muscular, and are inserted into the upper borders of the angles of the first six ribs and into the dorsum of the transverse process of the seventh cervical vertebra.

**ILIOCOSTALIS CERVICIS.** The iliocostalis cervicis (Figs. 6-19; 6-21) arises from the angles of the third, fourth, fifth, and sixth ribs, medial to the insertions of the iliocostalis thoracis, and is inserted into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebrae.

**Action.** The iliocostalis muscles are all extensors of the vertebral column and are also able to bend the column to one side (lateral flexion) and assist in its rotation. Additionally, the iliocostalis lumborum can depress the ribs.

**Nerves.** The iliocostalis muscles are supplied segmentally by branches of the dorsal primary divisions of the **spinal nerves**.

Longissimus (intermediate column)  
     Longissimus thoracis  
     Longissimus cervicis  
     Longissimus capitis

The longissimus is placed intermediately between the iliocostalis and the spinalis. It is the largest and the longest of the three columns comprising the erector spinae.

**LONGISSIMUS THORACIS.** The longissimus thoracis (Fig. 6-19) separates from the iliocostalis lumborum and spinalis thoracis in the upper lumbar region. Below this level it is still blended with the rest of the erector spinae, and some of its fibers are attached to the whole length of the posterior surfaces of the transverse processes and the accessory processes of the lumbar vertebrae, and to the anterior layer of the thoracolumbar fascia. In the thoracic region it is inserted by rounded tendons onto the tips of the transverse processes of all the thoracic vertebrae, and by fleshy processes to the lower nine or ten ribs between their tubercles and angles.

**LONGISSIMUS CERVICIS.** The longissimus cervicis (Figs. 6-19; 6-21), situated medial to the longissimus thoracis, arises by long thin tendons from the tips of the transverse processes of the upper four or five thoracic vertebrae, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the second to the sixth cervical vertebrae.

**Action.** The longissimus thoracis and longissimus cervicis extend the vertebral column and bend it to one side. The longissimus thoracis is also able to depress the ribs.

**Nerves.** The longissimus thoracis and longissimus cervicis are supplied by branches of the dorsal primary divisions of the spinal nerves.

**LONGISSIMUS CAPITIS.** The longissimus capitis (Figs. 6-19; 6-21) lies between the longissimus cervicis and the semispinalis capitis. It arises by tendons from the transverse processes of the upper four or five thoracic vertebrae, and the articular processes of the last three or four cervical vertebrae. It is inserted into the posterior margin of the mastoid process, deep to the splenius capitis and sternocleidomastoid. In the upper part of the neck, where the longissimus capitis and cervicis diverge toward their insertions, they are crossed by the splenius cervicis. The insertion of the splenius cervicis separates the insertion of the longissimus capitis from that of the longissimus cervicis. The longissimus capitis generally has a transverse tendinous inscription near its insertion.

**Action.** The *longissimus capitis* extends the head. The muscle of one side acting alone bends the head to the same side and rotates the face toward that side.

**Nerves.** The *longissimus capitis* is supplied by branches of the dorsal primary divisions of the **middle and lower cervical nerves**.

Spinalis (medial column)  
 Spinalis thoracis  
 Spinalis cervicis  
 Spinalis capitis

The spinalis column of muscles is the least massive of the three divisions of the erector spinae, and it is situated most medially and adjacent to the vertebral column.

**SPINALIS THORACIS.** The *spinalis thoracis* (Fig. 6-19) is the medial continuation of the erector spinae and is scarcely separable as a distinct muscle. It is situated at the medial side of the *longissimus thoracis*, with which it is intimately blended. It arises by three or four tendons from the spinous processes of the first two lumbar and the last two thoracic vertebrae. These unite to form a long, slender muscle which is inserted by separate tendons into the spinous processes of the upper thoracic vertebrae, the number varying from four to eight. It is intimately united with the *semispinalis thoracis* situated deep to it.

**SPINALIS CERVICIS.** The *spinalis cervicis* (Fig. 6-21) is an inconstant muscle that arises from the caudal part of the *ligamentum nuchae*, the spinous process of the seventh cervical, and sometimes from the spines of the first and second thoracic vertebrae, and is inserted into the spinous process of the axis, and occasionally into the spines of the two vertebrae caudal to it.

**SPINALIS CAPITIS.** The *spinalis capitis* is usually inseparably connected with the medial part of the *semispinalis capitis*. It arises and inserts with the *semispinalis capitis*, but it may have some separate attachments below to the upper thoracic vertebral spines.

**Actions.** The *spinalis muscles* extend the vertebral column.

**Nerves.** The *spinalis muscles* are innervated by branches of the dorsal primary divisions of the **spinal nerves**.

### *Transversospinalis Group*

The muscles in this group are more deeply placed than the erector spinae and they fill the concave region between the spinous processes and the transverse processes of the vertebrae. They consist of muscular fascicles that course obliquely upward and medially from the transverse processes to higher spinous processes. The *semispinalis*, *multifidus*, and *rotatores* muscles are included in this group.

Semispinalis muscles  
 Semispinalis thoracis  
 Semispinalis cervicis  
 Semispinalis capitis

The *semispinalis* muscles are found only in the thoracic and cervical regions extending to the head. They underlie the *spinalis* and *longissimus* columns of the erector spinae.

**SEMISPINALIS THORACIS.** The *semispinalis thoracis* (Fig. 6-19) consists of thin, narrow, fleshy fasciculi, interposed between tendons of considerable length. It arises by a series of tendons from the transverse processes of the sixth to the tenth thoracic vertebrae, and is inserted by tendons into the spinous processes of the first four thoracic and last two cervical vertebrae.

**SEMISPINALIS CERVICIS.** This muscle (Figs. 6-19; 6-21), thicker than the preceding, arises by a series of tendinous and fleshy fibers from the transverse processes of the first five or six thoracic vertebrae. Ascending in the neck and becoming thicker and more muscular, it is inserted into the cervical spinous processes from the axis to the fifth cervical vertebra inclusive. The fasciculus connected with the axis is the largest, and is chiefly muscular in structure. This muscle is almost entirely covered by the *semispinalis capitis*.

**Action.** The *semispinalis thoracis* and *semispinalis cervicis* extend the vertebral column and rotate it toward the opposite side.

**Nerves.** The *semispinalis thoracis* and *semispinalis cervicis* are supplied by branches of the dorsal primary divisions of **thoracic and cervical spinal nerves**.

**SEMISPINALIS CAPITIS.** The *semispinalis capitis* (Figs. 6-19; 6-20) is a large muscle situated on the posterior aspect of the neck, deep to the *splenius*, and medial to the *long-*

**Fig. 6-20.** The deep back muscles, showing some of the transversospinalis and interspinalis-intertransverse muscles. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, Urban & Schwarzenberg, 11th Ed., Vol. 1, 1975.)

gissimus cervicis and longissimus capitis. It arises by a series of tendons from the tips of the transverse processes of the first six or seven thoracic and the seventh cervical vertebrae, and from the articular processes of the fourth, fifth, and sixth cervical vertebrae.

The tendons unite to form a broad muscle, which passes almost vertically upward to be inserted between the superior and inferior nuchal lines of the occipital bone. The medial part, usually more or less distinct from the remainder of the muscle, is frequently

indistinguishable from the **spinalis capitis** muscle. This part is also called the **biventer cervicis** because it is traversed by an imperfect tendinous intersection.

**Action.** The **semispinalis capitis** extends the head and rotates it so that the face is turned toward the opposite side.

**Nerves.** The **semispinalis capitis** receives innervation from branches of the dorsal primary divisions of the **cervical nerves**.

**MULTIFIDUS MUSCLE.** The multifidus muscle (Figs. 6-20; 6-21) consists of a number of fleshy and tendinous fasciculi that fill the groove on both sides of the spinous processes of the vertebrae from the sacrum to the axis. The fascicles lie deep to the erector spinae in the lumbar region and deep to the **semispinalis thoracis** and **semispinalis cervicis** more superiorly. In the sacral region, these fasciculi arise from the back of the sacrum, as low as the fourth sacral foramen, from the aponeurosis of origin of the erector spinae, from the medial surface of the posterior superior iliac spine, and from the posterior sacroiliac ligaments; in the lumbar region (Fig. 6-20), from all the mamillary processes; in the thoracic region, from all the transverse processes; and in the cervical region (Fig. 6-21), from the articular processes of the lower four cervical vertebrae. Each fasciculus ascends obliquely, crossing over two to four vertebrae in its course toward the midline, and is inserted onto the spinous process of a higher vertebra. The fascicles vary in length and depth of position, but insertions are made onto the spines of all the vertebrae from the lowest lumbar to the axis. The longest and most superficial pass from one vertebra to the fifth or fourth above; those somewhat deeper are shorter and cross three vertebrae; the deepest and shortest cross two.

**Action.** Acting alone, the **multifidus** muscle bends (or laterally flexes) the vertebral column and rotates it to the opposite side. When the multifidus of each side acts together, the vertebral column is extended.

**Nerves.** The multifidus is innervated segmentally by branches of the dorsal primary divisions of the **spinal nerves**.

#### Rotatores muscles

- Rotatores thoracis
- Rotatores cervicis
- Rotatores lumborum

The rotatores are the deepest muscles of the transversospinalis group. Some cross one vertebra in their oblique course (**rotatores longi**), while others insert in the next succeeding vertebra and course in an almost horizontal direction (**rotatores brevis**). Although they are found along the entire length of the vertebral column, they are only developed to any degree in the thoracic region.

**ROTATORES THORACIS.** These narrow rectangular muscles (Fig. 6-20) form the deepest layer in the groove between the spinous and transverse processes of the thoracic vertebrae. They arise from the transverse process of one vertebra and insert at the base of the spine of the thoracic vertebra immediately above, or the one above that. They lie deep to the multifidus and cannot be distinguished readily from its deepest fibers.

**ROTATORES CERVICIS AND LUMBORUM.** In the cervical and lumbar regions the rotatores are less well defined and more variable. In the cervical region these muscular fascicles course from the articular processes below to the base of the spines above, while in the lumbar region they attach to the mamillary process below and to the inferior margin of the lamina above.

**Action.** The **rotatores** extend the vertebral column and rotate it toward the opposite side.

**Nerves.** The rotatores are supplied by branches of the dorsal primary divisions of the **spinal nerves**.

#### Interspinal-Intertransverse Group

In this group are muscles that pass segmentally from one vertebra to the next. The muscles considered in this group are the interspinales and the intertransversarii. Certain of the rotators also pass between adjacent vertebrae (**rotatores brevis**), but they are better classified with the transversospinal muscles because of their attachments and rotator action.

#### Interspinales muscles

- Interspinales cervicis
- Interspinales thoracis
- Interspinales lumborum

The interspinales are short, paired muscular fasciculi, placed between the spinous processes of the contiguous vertebrae, one on each side of the interspinal ligament.

**FIG. 6-21.** The deep muscles of the posterior cervical region. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, Urban & Schwarzenberg, 11th Ed., Vol. 1, 1975.)

**INTERSPINALES CERVICIS.** In the cervical region (Figs. 6-20; 6-21), the interspinales are most distinct and consist of six pairs, the first being situated between the axis and third vertebra, and the last between the seventh cervical and the first thoracic. They are small narrow bundles, attached to the apices of the adjacent spinous processes.

**INTERSPINALES THORACIS.** In the thoracic region the interspinales are found between the first and second vertebrae, and sometimes between the second and third, and be-

tween the eleventh and twelfth. They are generally undeveloped between the other thoracic spines.

**INTERSPINALES LUMBORUM.** In the lumbar region, there are four pairs in the intervals between the five lumbar vertebrae. There is also occasionally one pair between the last thoracic and first lumbar, and another between the fifth lumbar and the sacrum.

**Action.** The interspinales extend the vertebral column.

**Nerves.** The interspinales are supplied by branches of the dorsal primary divisions of the spinal nerves.

The **extensor coccygis** is a slender muscular fasciculus that is not always present. It extends over the caudal part of the posterior surface of the sacrum and coccyx, and *arises* by tendinous fibers from the last segment of the sacrum, or first piece of the coccyx. It passes caudally to be *inserted* into the lower part of the coccyx, and is a rudiment of the extensor muscle of the caudal vertebrae in lower animals.

#### Intertransversarii muscles

- Intertransversarii anterior cervicis
- Intertransversarii posterior cervicis
- Medial and Lateral
- Intertransversarii thoracis
- Intertransversarii medial lumborum
- Intertransversarii lateral lumborum

The intertransversarii are small, rounded, tendinous muscles placed between the transverse processes of contiguous vertebrae.

**INTERTRANSVERSarii CERVICIS.** The intertransversarii are best developed in the cervical region where at each segment there are paired anterior and posterior muscles. The **anterior cervical intertransverse muscles** interconnect the anterior tubercles of contiguous transverse processes of the cervical vertebrae, while those interconnecting the posterior tubercles are the **posterior cervical intertransverse muscles**. The ventral primary division of the segmental cervical nerve lies in a groove between the anterior and posterior muscles at each level. The posterior intertransverse muscles each consist of a medial and lateral part. The *medial part* belongs to the intrinsic muscles of the back and lies between the transverse processes, close to the vertebral body, and therefore is supplied by the posterior primary ramus of the spinal nerve. The *lateral part* attaches the transverse processes more laterally and, along with the anterior intertransverse muscles, is homologous to the intercostal muscles. Both of these latter elements are therefore supplied by the anterior primary ramus of the spinal nerve. There are seven pairs of cervical intertransverse muscles, the most superior being between the atlas and axis, and the lowest pair between the seventh cervical and first thoracic vertebrae.

**INTERTRANSVERSarii THORACIS.** In the thoracic region, the intertransverse muscles consist of single slips on each side. They are

present between the transverse processes of the last three thoracic vertebrae, and between the transverse processes of the last thoracic and the first lumbar. They are comparable to the medial part of the posterior cervical intertransverse muscles and are therefore supplied by the posterior primary rami of the thoracic nerves.

**INTERTRANSVERSarii LUMBORUM.** In the lumbar region (Fig. 6-20) the intertransverse muscles are once again arranged in pairs on each side of the vertebral column. One muscle of each pair, the **medial intertransverse muscle**, passes from the accessory process of one vertebra to the mammillary process of the vertebra below. These are intrinsic deep back muscles supplied by the dorsal primary division of the lumbar nerves. The other muscle of each pair is the **lateral intertransverse muscle**, and it occupies the entire interspace between the transverse processes of contiguous vertebrae. The lateral intertransverse muscles are themselves separable into posterior and anterior parts, which are homologues of the intercostal muscles, and both parts are innervated by branches of the anterior primary rami of the lumbar nerves.

**Action.** The intertransversarii bend the vertebral column laterally when acting on one side and extend the vertebral column when acting on both sides.

**Nerves.** Supplied by ventral primary rami of spinal nerves are the:

- (a) anterior cervical intertransverse muscles;
- (b) lateral part of the posterior cervical intertransverse muscles;
- (c) lateral (lumbar) intertransverse muscles.

Supplied by dorsal primary rami of spinal nerves are the:

- (a) medial part of the posterior cervical intertransverse muscles;
- (b) thoracic intertransverse muscles;
- (c) medial (lumbar) intertransverse muscles.

#### SUBOCCIPITAL MUSCLES

The suboccipital muscles, four on each side, lie deep to the semispinalis capitis in the uppermost part of the dorsal cervical region.

- Rectus capitis posterior major
- Rectus capitis posterior minor
- Obliquus capitis inferior
- Obliquus capitis superior

**RECTUS CAPITIS POSTERIOR MAJOR.** This muscle (Figs. 6-21; 6-22) arises by a pointed tendon from the spinous process of the axis. Becoming broader as it ascends, it is inserted into the lateral part of the inferior nuchal line of the occipital bone and the surface of the bone immediately inferior to the line. As the muscles of the two sides pass upward and laterally, the triangular space between them is occupied by the rectus capitis posterior minor muscles.

**Action.** The *rectus capitis posterior major* extends the head and rotates it to the same side.

**Nerve.** The *rectus capitis posterior major* is supplied by a branch of the dorsal ramus of the **suboccipital nerve** (first cervical nerve).

**RECTUS CAPITIS POSTERIOR MINOR.** This muscle (Figs. 6-21; 6-22) arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas. Widening as it ascends, it is inserted into the medial part of the inferior nuchal line of the occipital bone and the bony surface between the line and the foramen magnum.

**Action.** The *rectus capitis posterior minor* extends the head.

**Nerve.** This muscle also is supplied by a branch of the dorsal primary division of the **suboccipital nerve**.

**OBLIQUUS CAPITIS INFERIOR.** This muscle is the larger of the two oblique muscles and

FIG. 6-22. The left suboccipital triangle and muscles.

it arises from the apex of the spinous process of the axis (Figs. 6-21; 6-22). Passing laterally and slightly upward, it is inserted into the inferior and dorsal part of the transverse process of the atlas.

**Action.** The *obliquus capitis inferior* rotates the atlas and thereby turns the face toward the same side.

**Nerve.** This muscle is supplied by a branch of the dorsal primary division of the *suboccipital nerve*.

**OBLIQUUS CAPITIS SUPERIOR.** This muscle (Figs. 6-21; 6-22) arises by narrow tendinous fibers from the superior surface of the transverse process of the atlas, and thus joins with the insertion of the *obliquus capitis inferior*. It passes upward and slightly medially to be inserted into the occipital bone, between the superior and inferior nuchal lines, lateral to the *semispinalis capitis*.

**Action.** The *obliquus capitis superior* extends the head and bends it laterally.

**Nerve.** As are the other muscles in this group, the *obliquus capitis superior* is supplied by a branch of the dorsal primary division of the *suboccipital nerve*.

**SUBOCCIPITAL TRIANGLE.** Between the *obliquus capitis superior* and the *rectus capitis posterior major* is the *suboccipital triangle*. It is bounded *superiorly* and *medially* by the *rectus capitis posterior major*; *superiorly* and *laterally* by the *obliquus capitis superior*; *inferiorly* and *laterally* by the *obliquus capitis inferior*. The triangle is covered by dense, fibrous and fatty tissue, and it is situated deep to the *semispinalis capitis*. The floor of the triangle is formed by the posterior atlanto-occipital membrane and the posterior arch of the atlas. In the deep groove on the surface of the posterior arch of the atlas are the *vertebral artery* and the *first cervical* or *suboccipital nerve* (Fig. 6-22).

## MUSCLES OF THE THORAX

The muscles considered in this section are all attached to the ribs and concerned with rib movements, especially in relation to respiration. Although many other muscles also attach to the thorax, these are described in sections dealing with the upper extremity, abdomen, back, and neck, with which they are more specifically identified.

Intercostales externi  
Intercostales interni  
Intercostales intimi  
Subcostales

Transversus thoracis  
Levatores costarum  
Serratus posterior superior  
Serratus posterior inferior  
Diaphragm  
Diaphragmatic openings

## Fasciae

The superficial fascia and the outer layers of deep fascia of the thorax are described with the pectoral region and back. The thoracic cage proper, composed of ribs and intercostal muscles, is covered internally and externally by thin layers of deep fascia. The outer layer essentially forms a covering over the external intercostal muscles, while the internal layer, consisting of loose areolar tissue, is called the **endothoracic fascia**.

**ENDOTHORACIC FASCIA.** The endothoracic fascia is a deep investing fascial layer that lines the internal aspect of the thoracic cage. It covers the inner surface of the intercostal muscles and the intervening ribs, along with the subcostal and transverse thoracic muscles and the diaphragm. It lies between the parietal pleura and the thoracic cage, which in the absence of adhesions can therefore be easily separated. Dorsally, the endothoracic fascia is continuous over the bodies of the vertebrae and the intervertebral discs. In this mediastinal region, certain structures such as the azygous and hemiazygous veins, the thoracic duct, the sympathetic chain, and the splanchnic nerves are partially or completely surrounded by the fascia. Superiorly, it extends over the apices of the lungs where, somewhat thickened, it forms the **suprapleural membrane**, which is also called Sibson's fascia.<sup>1</sup> Inferiorly, it thins considerably over the superior surface of the diaphragm, but is continuous with the internal investing fascia of the abdominal cavity, the **fascia transversalis**, dorsal to the diaphragm at the lumbocostal arches and through the aortic hiatus.

## Muscles

The **intercostales muscles** (Figs. 6-23; 6-24) are thin layers of muscular and tendinous fibers occupying each of the intercostal

<sup>1</sup>Francis Sibson (1814-1876): An English physician and anatomist (London).

**FIG. 6-23.** Longitudinal section of the thoracic wall. Note the position of the intercostal vein, artery and nerve in the sulcus of the rib, and that these structures course around the trunk between the innermost (intimi) and internal intercostal muscle layers. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban & Schwarzenberg, 11th Ed., Vol. 1, 1975.)

spaces. They are named **external**, **internal**, and **innermost** (intimi) from their surface relations, the external being the most superficial and the innermost being the deepest, while the internal intercostal muscles lie between the other two.

**INTERCOSTALES EXTERNI.** There are eleven external intercostal muscles on each side. They extend in the intercostal spaces from the tubercles of the ribs dorsally to the cartilages of the ribs ventrally (Fig. 6-23), where each ends in a thin, fibrous sheet, the **external intercostal membrane**, which continues forward to the sternum. Each external intercostal muscle arises from the lower border of a rib and is inserted into the upper border of the rib below. In the lowest two spaces the muscles extend to the ends of the cartilages, and in the uppermost two or three spaces they do not quite reach the ends of the ribs. They are thicker than the intercostales interni, and their fibers are directed obliquely inferolaterally on the dorsum of the thorax, and inferomedially and somewhat ventrally on the anterior aspect of the thorax.

**Action.** The actions of the **external intercostal muscles** are not clearly understood. There is reasonable evidence to support the view that at least some of these muscles are active during inspiration and that they elevate the ribs. Apparently, however, they are also active during the early phase of expiration.

**Nerves.** The external intercostal muscles are innervated by the **intercostal nerves**, numbered sequentially according to the interspace, e.g., the fourth intercostal nerve supplies the muscles occupying the fourth intercostal space between the fourth and fifth ribs.

**Variations.** At times muscular slips join the external intercostal muscles to the external oblique or serratus anterior muscle. A **supracostalis muscle**, extending from the anterior end of the first rib down to the second, third, or fourth rib, occasionally is seen.

**INTERCOSTALES INTERNI.** There are also eleven internal intercostal muscles on each side. They commence anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and at the anterior extremities of the cartilages of the false ribs. They extend posteriorly as far as the angles of the ribs, where they are continued to the

vertebral column by thin aponeuroses, the **internal intercostal membranes**. Each muscle arises from the ridge on the inner surface of a rib, as well as from the corresponding costal cartilage, and is inserted into the upper border of the rib below (Figs. 6-23; 6-24). Their fibers are also directed obliquely, but pass in a direction perpendicular to those of the external intercostal muscles.

**Action.** The **internal intercostal muscles** are also involved in respiratory movements. The portion of the upper four or five muscles that interconnects the costal cartilages is thought to elevate the ribs (as occurs with the external intercostals) during inspiration. The more lateral and dorsal portions of the muscles, where the fibers are oriented more obliquely in direction (inferiorly and posteriorly), are active during expiration. Some doubt still exists about these generally described actions.

**Nerves.** The **intercostal nerves** innervate the internal as well as the external intercostal muscles.

**INTERCOSTALES INTIMI.** These innermost intercostal muscles are frequently considered to be the deepest parts of the internal intercostal muscles. They lie deep to the intercostal vessels and nerves, being interposed between these structures and the parietal pleura (Fig. 6-23). They extend between the costal groove of the rib above to the inner lip of the upper margin of the rib below. They are not well developed and may, in fact, even be absent in the upper four or five interspaces. Their fibers generally course in the same direction as those of the internal intercostal muscles.

**Action.** It may be that the action of the **innermost intercostals** is similar to that of the internal intercostals, but conclusive data in this regard do not exist.

**Nerves.** Like the other intercostal muscles, the innermost muscles are supplied by the **intercostal nerves**.

**SUBCOSTALES MUSCLES.** The subcostal muscles consist of oblique muscular and aponeurotic fasciculi which are usually well developed only in the lower part of the thorax. Each arises from the inner surface of one rib, dorsally near its angle, and is inserted onto the inner surface of the second or third rib below. Their fibers run in the same direction as those of the innermost intercostals and similarly separate the intercostal vessels and nerves from the pleura.

**Action.** The **subcostales** probably draw adjacent ribs together. With the last rib fixed by the quadratus lumborum, they may lower the ribs, decreasing the volume of the thoracic cavity.

**Nerves.** Like the intercostal muscles, the subcostales are supplied by the **intercostal nerves**.

**TRANSVERSUS THORACIS.** The transversus thoracis muscle is a thin plane of muscular and tendinous fibers situated on the inner surface of the anterior wall of the chest (Fig. 6-24). It arises on each side from the caudal third of the inner surface of the body of the sternum, from the inner surface of the xiphoid process, and from the inner surface of the costal cartilages of the third through the sixth ribs at their sternocostal junctions. Its fibers diverge as they pass superiorly and laterally, to be inserted by slips into the caudal borders and inner surfaces of the costal cartilages of the second, third, fourth, fifth, and sixth ribs. The lowest fibers of this muscle are horizontal and are continuous with those of the transversus abdominis; the intermediate fibers are oblique, while the highest fibers are almost vertical. This muscle varies in its attachments, not only in different subjects, but on opposite sides of the same subject.

**Action.** The **transversus thoracis** draws the ribs downward.

**Nerves.** This muscle is also supplied by branches of the **intercostal nerves**.

**LEVATORES COSTORUM.** There are twelve levatores costorum muscles on each side of the posterior surface of the thoracic cage (Figs. 6-19 to 6-21). They are tendinous and fleshy bundles that arise from the ends of the transverse processes of the seventh cervical and upper eleven thoracic vertebrae. The muscles pass obliquely inferolaterally like the fibers of the external intercostals in this dorsal region, and each is inserted into the outer surface of the rib immediately below the vertebra from which it takes origin, between the tubercle and the angle (**levatores costarum breves**). Each of the four most inferior muscles divides into two fasciculi, one of which is inserted as described above; the other descends to the second rib below its origin (**levatores costarum longi**).

**FIG. 6-24.** The posterior surface of the anterior thoracic wall viewed from within. Note the transverse thoracic muscle on each side, as well as the descending internal thoracic vessels from which branch the anterior intercostal arteries and veins.

**Action.** The *levator costorum* elevate the ribs and bend the vertebral column laterally, rotating it slightly toward the opposite side.

**Nerves.** The *levator costorum* are supplied by branches from the intercostal nerves.

**SERRATUS POSTERIOR SUPERIOR.** This thin, quadrilateral muscle is situated on the dorsal and upper part of the thorax. It arises by a thin and broad aponeurosis from the lower part of the ligamentum nuchae, from the spinous processes of the seventh cervical and first two or three thoracic vertebrae, and from the supraspinal ligament. Inclining inferiorly and laterally, it becomes muscular and is inserted by four, fleshy digitations into the cranial borders of the second, third, fourth, and fifth ribs, a little beyond their angles.

**Action.** The *serratus posterior superior* elevates the upper ribs.

**Nerves.** This muscle is supplied by branches of the ventral primary divisions of the first four thoracic nerves.

**Variations.** There may be an increase or decrease in size and number of slips or an entire absence of the muscle.

**SERRATUS POSTERIOR INFERIOR.** This thin, irregularly quadrilateral muscle is situated at the junction of the thoracic and lumbar regions. It is broader than the preceding muscle and is separated from it by about four ribs. The *serratus posterior inferior* arises by a thin aponeurosis from the spinous processes of the last two thoracic and first two or three lumbar vertebrae, and from the supraspinal ligament. Passing obliquely upward and laterally, it becomes fleshy and

divides into four flat digitations which are inserted into the inferior borders of the last four ribs, a little lateral to their angles. The thin aponeurosis of origin is intimately blended with the thoracolumbar fascia and the aponeurosis of the latissimus dorsi.

**Action.** The *serratus posterior inferior* draws the ribs to which it is attached outward and downward, counteracting the inward pull of the diaphragm.

**Nerves.** This muscle is supplied by branches of the ventral primary divisions of the **ninth to twelfth thoracic nerves**.

**THE DIAPHRAGM.** The diaphragm is a dome-shaped musculofibrous septum that separates the thoracic from the abdominal cavity (Figs. 6-24; 6-25). Its convex upper surface forms the floor of the thorax, and its concave inferior surface forms the roof of the abdomen. Its peripheral part consists of muscular fibers that take origin from the cir-

cumference of the thoracic outlet and converge to be inserted into a central tendon.

The muscular fibers may be grouped according to their origins into three parts—**sternal**, **costal**, and **lumbar**. The **sternal part** arises by two fleshy slips from the dorsum of the xiphoid process; the **costal part** arises from the inner surfaces of the cartilages and adjacent portions of the last six ribs on each side, interdigitating with the transversus abdominis; and the **lumbar part** arises from two aponeurotic arches on each side, named the **medial** and **lateral arcuate ligaments**, and from the lumbar vertebrae by two pillars or **crura**. The two crura are interconnected at the midline by a tendinous arch called the **median arcuate ligament** which lies just in front of the aorta.

The **medial arcuate ligament** (*medial lumbocostal arch*) is a tendinous arch in the fascia covering the upper part of the *psos major*. Medially, it is continuous with the lateral tendinous margin of the correspond-

FIG. 6-25. The diaphragm. Abdominal surface.

ing crus, and is attached to the side of the body of the first or second lumbar vertebra. Laterally, it is fixed to the front of the transverse process of the first, and sometimes also to that of the second, lumbar vertebra.

The **lateral arcuate ligament** (*lateral lumbo-costal arch*) is a thickened tendinous band across the upper part of the quadratus lumborum. It is attached medially to the ventral surface of the transverse process of the first lumbar vertebra, and laterally to the tip and inferior margin of the twelfth rib.

The **crura of the diaphragm** are tendinous in structure, and blend with the anterior longitudinal ligament of the vertebral column. The **right crus**, somewhat wider and longer than the left, arises from the anterior surfaces of the bodies and intervertebral fibrocartilages of the first three lumbar vertebrae, while the **left crus** arises from the corresponding parts of the first two lumbar vertebrae only. The medial tendinous margins of the crura pass anteriorly and medially, meet in the midline, and form the median arcuate ligament, which crosses the ventral aspect of the aorta and is often poorly defined.

From this series of origins the fibers of the diaphragm converge to be inserted into the central tendon. The fibers arising from the xiphoid process are short and occasionally aponeurotic. Those from the medial and lateral arcuate ligaments, and more especially those from the ribs and their cartilages, are longer and describe marked curves as they ascend and converge to their insertion. The fibers of the crura diverge as they ascend, the most lateral being directed upward and laterally to the central tendon. The medial fibers of the right crus ascend on the *left side* of the esophageal hiatus, and occasionally a fasciculus of the left crus crosses the aorta and runs obliquely through these fibers of the right crus toward the vena caval foramen.

The **central tendon** of the diaphragm is a thin but strong aponeurosis situated near the center of the muscle, but somewhat closer to the anterior than to the dorsal part of the thorax, so that the dorsal muscle fibers are longer. The tendon is situated immediately below the pericardium, with which it is partially blended. It is shaped somewhat like a clover leaf, consisting of three divisions or leaflets separated from one another by slight indentations. The right leaflet is the largest; the middle is directed toward the xiphoid

process and is the next in size; and the left is the smallest. In structure the tendon is composed of several planes of fibers, which intersect at various angles and unite into straight or curved bundles, an arrangement that affords considerable strength to the muscle.

**Diaphragmatic Openings.** The diaphragm is pierced by a series of apertures that permit the passage of structures between the thorax and the abdomen. Three large openings, the **aortic**, the **esophageal**, and the **vena caval**, are found along with a series of smaller ones (Fig. 6-25).

The **aortic hiatus** is the most inferior and posterior of the large apertures. It lies just to the left of the midline at the level of the twelfth thoracic vertebra. Strictly speaking, it is not an aperture in the diaphragm but an osseoaponeurotic opening between it and the vertebral column, and therefore behind the diaphragm. Occasionally some tendinous fibers are prolonged across the bodies of the vertebrae from the medial parts of the lower ends of the crura and pass behind the aorta, thus converting the hiatus into a true fibrous ring. The hiatus is bounded anteriorly by the crura and posteriorly by the body of the first lumbar vertebra, and through it pass the aorta and the thoracic duct. Usually the aortic hiatus also transmits a vein connecting the right ascending vein to the azygos vein, while the azygos vein passes through the right crus. At times, however, the azygos vein passes through the hiatus itself to the right of the aorta.

The **esophageal hiatus** is elliptical in shape and is situated in the muscular part of the diaphragm at the level of the tenth thoracic vertebra. It is placed superior, anterior, and a little to the left of the aortic hiatus, and transmits the esophagus, the vagus nerves, and esophageal branches of the left gastric artery and vein.

The **vena caval foramen** is the most superior of the large apertures and is situated at about the level of the intervertebral disc that lies between the eighth and ninth thoracic vertebrae. The opening is quadrilateral in shape, and is placed at the junction of the right and middle leaflets of the central tendon, so that its margins are tendinous. It transmits the inferior vena cava, the wall of which is adherent to the margins of the foramen and some branches of the right phrenic nerve.

Of the lesser apertures, two in the right crus transmit the greater and lesser right splanchnic nerves, while three in the left crus give passage to the greater and lesser left splanchnic nerves and the hemiazygos vein. The ganglionated sympathetic chains usually enter the abdominal cavity behind the diaphragm and deep to the medial arcuate ligaments.

On each side two small intervals exist at which the muscular fibers of the diaphragm are deficient and are replaced by areolar tissue. One, between the sternal and costal parts, transmits the superior epigastric branch of the internal thoracic artery and some lymphatics from the abdominal wall and the convex surface of the liver. The other, between fibers springing from the medial and lateral arcuate ligaments, is less constant. When this interval does exist, the upper posterior part of the kidney is separated from the pleura by areolar tissue only.

**Action.** Acting from their attachments on the ribs and lumbar vertebrae, the muscle fibers of the **diaphragm** draw the central tendon downward and forward during inspiration. This action has two effects: (1) it tends to increase the volume and decrease the pressure within the thoracic cavity, and (2) it tends to decrease the volume and increase the pressure within the abdominal cavity. During inspiration, lowering of the diaphragm decreases the pressure within the thorax, and air is forced into the lungs through the open glottis of the larynx by the higher pressure of the atmosphere. At the same time, the descending diaphragm presses against the abdominal viscera, forcing them downward against the passive resistance of the abdominal and pelvic muscles, and causing the anterior abdominal wall to protrude slightly.

The pressure within the abdominal cavity is greatly increased when the abdominal muscles and the diaphragm contract actively at the same time. This increase in pressure tends to make the abdominal or pelvic viscera discharge their contents as in micturition, defecation, emesis, and parturition.

**Nerve.** The diaphragm is innervated by the **phrenic nerve** from the cervical plexus, containing mainly fibers from the fourth, but also some from the third and fifth cervical nerves.

**Variations.** The sternal portion of the diaphragm is sometimes absent, and more rarely defects occur in the lateral part of the central tendon or adjoining muscle fibers.

**Movements of Respiration.** The respiratory cycle of inspiration and expiration is the result of increases and decreases in the capacity of the thoracic cavity. **Inspiration**, which is the correlate of an increase in the volume of the cavity, results from

muscular action and is brought about in two ways: (1) by the descent of the diaphragm due to contraction of its muscle, which increases the vertical dimension of the thorax and (2) by the action of certain muscles on the ribs, sternum, and vertebral column which increases the transverse and anteroposterior dimensions of the thorax. **Expiration**, associated with a decrease in the volume of the thoracic cavity, is primarily a passive process due to the elastic recoil of the thoracic wall and the tissues of the lungs and bronchi. Thoracic volume may also decrease, however, as the result of muscular action, in which case (1) the abdominal muscles force the diaphragm upward by increasing the abdominal pressure, and (2) the thoracic wall is actively contracted by the action of certain muscles on the ribs and vertebral column.

**Quiet inspiration** results from diaphragmatic contraction which increases the vertical diameter of the thoracic cavity. The first and second ribs remain fixed by the inertia and resistance of the cervical structures, but the remaining ribs, except the last two, are brought upward toward them by the contraction of the external intercostal muscles. The upward motion of the ribs, due to their position and to the obliquity of their axis of rotation, enlarges the anteroposterior and transverse diameters of the thorax. Thus, quiet inspiration consists of both diaphragmatic and costal components. Diaphragmatic breathing is also called abdominal because the visible result of contraction of the diaphragm is protrusion of the abdominal wall. To contrast with this, costal breathing has also been called thoracic breathing.

In the newborn child, the ribs are virtually horizontal and, therefore, are already in the position of full inspiration. Breathing in the baby is entirely dependent upon diaphragmatic action and abdominal movements may easily be perceived. As the child develops, the ribs become more oblique, and costal movements with respiration result in the development of thoracic breathing. In the adult, both abdominal and thoracic breathing are observed, but one or the other may predominate. Breathing patterns can be altered with training and exercise.

Electromyographic studies indicate that both external and internal intercostal muscles are slightly active during quiet inspiration, but have no rhythmic increase and decrease, acting more to keep the ribs in a constant position than to expand the thorax. The scalene muscles, however, do show rhythmic activity (Jones, Beargie and Pauly, 1953).

**Quiet expiration** follows the relaxation of the inspiratory muscles, and the normal resting position of the thorax is that seen at the end of a quiet expiration. This position is restored without muscular effort by the recoil of structures that were displaced by the inspiratory act. The displacement of the anterior abdominal wall is overcome by the tonus of the abdominal muscles. The ribs are restored from their displacement by the elasticity of the ligaments and

cartilages that hold them in place. The extensive network of elastic fibers that permeates lung tissue retracts the lungs. The bronchial tree, which has been elongated by the descent of the diaphragm, helps to return the lungs to their resting position by its elastic recoil.

**Deep inspiration** requires the intensification of all the actions seen in quiet inspiration. Additionally, the first two ribs are raised by the scalene and sternocleidomastoid muscles, and the remaining ribs are raised more forcibly by the actions of the levatores costarum and the serratus posterior superior. The ribs are further elevated by a straightening of the vertebral column through contraction of the erector spinae muscle. After the abdominal viscera have been forced downward by the diaphragm to a considerable extent, the abdominal muscles offer resistance to further displacement. The viscera then may act as a point of fixation for the diaphragm, so that any further contraction raises the ribs.

**Forced inspiration** is observed in patients with great air hunger, and all the muscles of the body seem to coordinate to assist in breathing. The levator scapulae, the trapezius, and the rhomboids elevate and fix the scapula, which is then used as an origin by the pectoralis minor to draw the ribs upward. The patient frequently further fixes the shoulder girdle by grasping the back of a chair or end of the bed, so that the pectoralis major and the serratus anterior further elevate the ribs for a greater inspiratory effort.

**Forced expiration**, such as that necessary for sneezing and coughing, unlike quiet expiration, requires the action of muscles. The last two ribs are pulled downward and fixed by the quadratus lumborum, and the other ribs are also drawn downward by the internal intercostals and the serratus posterior inferior muscles. The muscles of the abdominal wall, by pressing on the abdominal viscera, force the diaphragm upward, and by flexing the vertebral column, assist in lowering the ribs.

**Position of the Diaphragm.** The height of the diaphragm is constantly changing during respiration, and it also varies with the degree of distension of the stomach and the intestines and with the size of the liver. After a forced expiration, the right cupola of the diaphragm is on a level anteriorly with the fourth costal cartilage, laterally with the fifth, sixth, and seventh ribs, and posteriorly with the eighth rib. The left cupola is a little lower than the right. The absolute range of movement of the diaphragm between deep inspiration and deep expiration averages in both males and females 30 mm on the right side and 28 mm on the left. In quiet respiration, the average movement is 12.5 mm on the right side and 12 mm on the left.

Radiography shows that the height of the diaphragm in the thorax varies considerably with the position of the body. It stands highest when the body is horizontal and the patient on his back, and in this position the diaphragm performs the largest res-

piratory excursions with normal breathing. When the body is erect, the dome of the diaphragm descends and its respiratory movements become smaller. The dome falls still lower when the sitting posture is assumed, and in this position, diaphragmatic excursions are the smallest. These facts explain why patients suffering from severe dyspnea are most comfortable and least short of breath when they sit up. When the body is horizontal and the patient on his side, the two halves of the diaphragm do not behave alike. The uppermost half sinks to a level lower than that when the patient sits, and moves little with respiration; the lower half rises higher in the thorax than it does when the patient is supine, and its respiratory excursions are greatly increased. In unilateral disease of the pleura or lungs, analogous interference with the position or movement of the diaphragm can generally be observed radiographically.

The position of the diaphragm in the thorax depends on three main factors: (1) the elastic retraction of the lung tissue, which tends to pull it upward; (2) the pressure exerted on its inferior surface by the viscera, which naturally tends to be a negative pressure or downward suction, when the patient sits or stands, and positive or upward pressure, when he reclines; (3) the intra-abdominal tension due to the abdominal muscles.

The following figures represent the average thoracic changes that occur during deepest possible inspiration. The manubrium sterni moves 30 mm in an upward and 14 mm in a forward direction; the width of the subcostal angle is increased by 26 mm at a level of 3 cm below the articulation between the body of the sternum and the xiphoid process; the umbilicus is retracted and drawn upward for a distance of 13 mm.

**Diaphragmatic Hernias.** At times abnormal openings in the diaphragm allow abdominal viscera to herniate into the thorax. The most common **congenital diaphragmatic hernia** results from an incomplete separation of the pleural and peritoneal cavities in the posterolateral region of the diaphragm. This occurs more frequently on the left than the right (Butler and Claireaux, 1962; Gray and Skandalakis, 1972), and allows the small intestine or other organs to enter the thorax through the incompletely closed pleuroperitoneal canal (of Bochdalek).<sup>1</sup>

Most **acquired diaphragmatic hernias** occur at the esophageal hiatus (hiatal hernia). In this condition the upper end of the stomach herniates into the thorax, so that it "slides" for some distance up and down through the esophageal hiatus. In other hiatal hernias, the cardiac end of the stomach may herniate into the thorax and carry with it the lower esophagus, thereby producing a U-shaped redundancy of the lower esophagus.

## FASCIAE AND MUSCLES OF THE ABDOMEN

The muscles of the abdomen may be divided into two groups: the **anterolateral muscles** and the **posterior muscles**.

### *Anterolateral Abdominal Muscles*

Obliquus externus abdominis  
Obliquus internus abdominis  
Cremaster  
Transversus abdominis  
Rectus abdominis  
Pyramidalis

## SUPERFICIAL ABDOMINAL FASCIA

The **superficial fascia** (Fig. 6-28) of the anterior abdominal wall is soft and movable, and likely to contain fat. It is continuous, superiorly, with the superficial fascia of the thorax; inferiorly, with that of the thigh and external genitalia; and laterally, it gradually becomes tougher and more resistant as it continues as the fascia of the back. Below the umbilicus the superficial fascia is unusually easy to separate into superficial and deep layers. Between the two layers are found the superficial vessels and nerves and the superficial lymph nodes. This uncommon divisibility and certain other peculiar features require that the two layers be described separately.

**SUPERFICIAL LAYER (FASCIA OF CAMPER<sup>1</sup>).** The superficial layer is thick, areolar in texture, and contains a variable amount of fat. It is a genuine panniculus adiposus, and may be several centimeters thick in obese individuals, in which case it also is likely to be irregularly divisible into laminae. It is continuous over the inguinal ligament with a similar and corresponding layer of the thigh. In the male, it continues down on the penis and scrotum, loses its fat and fuses with the deep layer. It assists in the formation of a special pale reddish fascia of these genital organs called the **dartos**, which also contains some nonstriated muscle fibers. In the female, it retains some adipose tissue as it is continued into the labia majora. In both sexes, it is prolonged dorsally in the crease between the external genitalia and the thigh

and becomes continuous with the outermost layer of superficial fascia in the perineum and medial surface of the thigh.

**DEEP LAYER (FASCIA OF SCARPA<sup>2</sup>).** The deep layer of superficial fascia is a membranous sheet that usually contains little or no adipose tissue. It is composed, in considerable part, of yellow elastic fibers, and probably corresponds to the tunica abdominalis, an elastic layer that contributes to the support of the inguinal mammae in some lower mammals. It forms a continuous sheet across the midline, but attaches to the linea alba as it crosses. *Superiorly and laterally*, it loses its identity as a special layer of the superficial fascia of the upper abdomen and back. *Inferiorly*, it passes over the inguinal ligament and is *securely attached*, either to the ligament itself or to the fascia lata of the thigh just beyond it. Inferior to the ligament, a corresponding layer, called the **fascia cribrosa**, covers and fills an opening, the **fossa ovalis**, for the passage of the great saphenous vein, where it enters the femoral vein. At the medial end of the inguinal ligament, Scarpa's fascia passes over the superficial inguinal ring without being attached and continues into the penis and scrotum. It continues along the crease between the scrotum (or labium majus) and thigh into the perineum where it is called the **fascia of Colles**.<sup>3</sup> As the superficial fascia courses deep to the skin of the scrotum and penis, its two layers are fused to form the dartos. Because the dartos also contains a layer of scattered smooth muscle cells, the scrotal skin is thrown into folds or rugae. In the midline over the symphysis pubis, Scarpa's fascia is thickened in the male by the addition of numerous closely set, strong bands which extend down to the dorsum and sides of the penis, forming the **fundiform ligament of the penis**.

The fascial cleft that separates the deep layer of the superficial fascia (Scarpa's) from the true deep fascia over the caudal portion of the aponeurosis of the obliquus externus muscle is quite definite and of considerable clinical interest because of its continuity with a similar cleft in the perineum. Thus,

<sup>1</sup>Petrus Camper (1722-1789): A Dutch physician and anatomist (Gröningen).

<sup>2</sup>Antonio Scarpa (1747-1832): A Venetian anatomist and ophthalmologist (Pavia).

<sup>3</sup>Abraham Colles (1773-1843): An Irish surgeon and anatomist (Dublin).

the possibility exists that extravasated urine from a ruptured urethra in the perineum can find its way into the scrotum, deep to the dartos, and then onto the anterior abdominal wall deep to Scarpa's fascia.

This fascial cleft is limited superiorly near the umbilicus because the superficial fascia (Scarpa's) becomes adherent to the deep fascia, and laterally because Scarpa's fascia attaches closely to the muscular portion of the external oblique. The cleft is limited, inferiorly and laterally, by the firm attachment of Scarpa's fascia either to the inguinal ligament or to the fascia lata just below it. Over the medial portion of the inguinal ligament and the superficial inguinal ring, however, Scarpa's fascia and the deep fascia are not attached, so that the cleft follows along the narrow crease between the scrotum (or labium) and thigh, and is continuous with the cleft between the superficial fascia of the perineum (Colles') and the deep fascia, called the inferior fascia of the urogenital diaphragm or the perineal membrane. From this groove, it is continuous medially with the cleft beneath the movable dartos of the scrotum and penis, but the cleft is abruptly limited laterally by an attachment to the deep fascia over the pubic ramus where the adductor muscles of the medial thigh originate. In obese individuals there may be accumulations of fat in the cleft deep to Scarpa's fascia. The superficial epigastric and superficial circumflex iliac blood vessels lie between Camper's and Scarpa's fasciae, but are attached to the superficial surface of Scarpa's layer.

#### DEEP ABDOMINAL FASCIA

The **outer investing layer** of deep fascia is easily identified in the lateral portion of the anterior abdominal wall where it covers the fleshy fibers of the external oblique muscle. It is continuous with the deep fascia covering the latissimus dorsi and pectoralis major. More medially, over the aponeurosis of the external oblique, the deep fascia is so firmly adherent that it may escape recognition. Its presence is easily demonstrated in dissection, however, by scraping it back until the glistening fibers of the aponeurosis beneath are revealed. Superiorly, it covers the upper end of the rectus sheath and is continuous with the pectoral fascia. Inferiorly, it is

firmly attached to the inguinal ligament and joins the deep fascia emerging from beneath that ligament to become the fascia lata of the thigh. It covers the superficial inguinal ring as a distinct and separate layer, and there, reinforced by the fascia of the inner surface of the external oblique aponeurosis, gives rise to a tubular prolongation, the external spermatic fascia, which is the coat of the spermatic cord and testis just deep to the dartos. Near the midline, the deep fascia is attached to the pubic bone and is then continuous with deep fascia investing the penis. At the lower end of the linea alba, the deep fascia is thickened into a strong, fibrous triangle, the **suspensory ligament of the penis**, which attaches the dorsum of the penis to the symphysis pubis and arcuate pubic ligament. At the medial end of the inguinal ligament, it is attached to the pubic ramus and arcuate pubic ligament and is then continuous posteriorly, over the ischiocavernosus muscle, with the deep fascia of the perineum. Laterally, beyond its attachment to the pubic ramus, it is continuous with the fascia covering the adductor muscles of the medial side of the thigh.

#### MUSCLES

**OBLIQUUS EXTERNUS ABDOMINIS.** The external oblique muscle, situated on the lateral and anterior parts of the abdomen, is the largest and the most superficial of the three flat muscles in this region (Fig. 6-26). It is broad, thin, and irregularly quadrilateral, and its muscular portion occupies the lateral wall of the abdomen, while its aponeurosis stretches across the anterior abdominal wall. It arises by eight fleshy digitations from the external surfaces and inferior borders of the lower eight ribs. These digitations are arranged sequentially and form an oblique line that runs downward and backward; the cranial ones are attached close to the cartilages of the corresponding ribs, the intermediate ones to the ribs at some distance from their cartilages, and the most caudal to the apex of the cartilage of the last rib. The five superior digitations increase in size from above downward and are received between corresponding muscular slips of the serratus anterior. The three lower ones diminish in size from above downward and receive between them corresponding mus-

cular digitations from the latissimus dorsi. From these attachments, the fleshy fibers proceed in a diverging manner to their insertions. The fasciculi from the last two ribs are nearly vertical and are inserted into the anterior half of the outer lip of the iliac crest; the upper and middle fasciculi, directed downward and forward, terminate in a broad aponeurosis along a line extending from the prominence of the ninth costal cartilage to the anterior superior iliac spine.

**Action.** The *obliquus externus abdominis* compresses the abdominal contents and assists in micturition, defecation, emesis, parturition, and forced expiration. Both sides acting together flex the vertebral column by drawing the pubis toward the xiphoid process. One side alone bends the vertebral column laterally and rotates it, bringing the shoulder of the same side forward.

**Nerves.** This muscle is supplied by branches of the **seventh to twelfth intercostal nerves**.

**Aponeurosis of Obliquus Externus Abdominis.** The aponeurosis of the external oblique muscle is a strong membrane formed by tendinous bundles in continuity with the muscle fibers of the external oblique. Initially, the aponeurotic fibers course downward and medially, covering the entire ventral surface of the abdomen and lying superficial to the rectus abdominis muscle, thereby helping to form its sheath. The fibers of the aponeurosis on each side are arranged in two layers, superficial and deep, which pass obliquely perpendicular to each other. Additionally, as the aponeurotic fibers cross the midline, they interlace with those of the opposite side in such a manner that the superficial fibers of one side extend as the direct continuation of the fibers of the deep layer of the opposite external oblique aponeurosis (Rizk, 1976). As the fibers pass across the midline, their sites of intersection form the **linea alba**, which extends from the xiphoid process to the symphysis pubis. The uppermost part of the aponeurosis serves as the origin for the inferior fibers of the pectoralis major. The lowermost portion ends in a tendinous border called the **inguinal ligament**. Although it is aponeurotic rather than ligamentous in function, it extends from the anterior superior spine of the ilium at its superolateral end to the pubic tubercle inferomedially (Figs. 6-26 to 6-31). Near its medial end, the free border is curled under

like a sling to support the spermatic cord. Its attachment to the pubic bone is fanned out along the pectineal line beyond the pubic tubercle to leave a crescentic, free border named the **lacunar ligament** (Fig. 6-27). In a small percentage of cases, other fibers may double back superiorly toward the linea alba deep to the main aponeurosis in a small triangular sheet called the **reflected inguinal ligament**. The tendinous bundles of the aponeurosis just above the inguinal ligament separate from each other at the pubic tubercle, leaving a narrow triangular opening called the **superficial inguinal ring**, through which passes the spermatic cord in a male or the round ligament in a female. The bundles bordering the ring are called the **superior and inferior crura**. Lateral to the opening the aponeurosis contains, in addition to the bundles running in the usual direction, some scattered, transverse, reinforcing strands that sweep superiorly and toward the midline in curved lines. These are called **intercrural fibers**. They are part of the aponeurosis and should not be confused with the intercrural fascia. In the foregoing description the aponeurosis has been treated as if it belonged solely to the external oblique muscle. This is advantageous for the presentation of the subcutaneous inguinal ring and associated structures, but it gives an incomplete picture because the aponeurosis serves also as the insertion of the internal oblique and transversus muscles, and it contributes, as well, to the formation of the sheath for the rectus abdominis muscle.

**Inguinal Ligament.** This ligament, formed by the lower border of the aponeurosis of the external oblique muscle, extends from the anterior superior iliac spine to the pubic tubercle. Its lateral half is firmly attached to a band in the iliac fascia where the latter is fused with the fascia innominata and transversalis fascia and continues into the thigh as the fascia lata. The medial portion of the ligament is a free border, and the femoral sheath and vessels pass deep to it on their way into the thigh. The medial fibers of the ligament curl under the adjacent aponeurosis to reach their insertion into the pectineal fascia and pubic bone lateral to the tubercle, thereby forming a narrow sling for support of the spermatic cord. The curved free border at this attachment is named the **lacunar ligament** (Fig. 6-27). At their attachment

FIG. 6-26. The obliquus externus abdominis muscle.

some fibers of the lacunar ligament continue lateralward along the pectineal line, producing a strong tendinous ridge called the **pectineal** (Cooper's<sup>1</sup>) **ligament** (Fig. 5-31).

**Lacunar Ligament.** The lacunar ligament (Figs. 5-31; 6-27) is that part of the medial end of the inguinal ligament which is rolled under the spermatic cord and is attached along the pectineal fascia just lateral to the pubic tubercle. When it is viewed through the superficial inguinal ring, after the spermatic cord has been removed, the lacunar ligament appears to be a triangular fibrous

membrane. Its crescentic free margin forms the base of the triangular membrane, and it is concave laterally. Its apex is directed medially at the pubic tubercle (Fig. 6-27), and the ligament measures slightly less than two centimeters from apex to base. It lies almost horizontally when the body is erect, and the spermatic cord rests on its superior surface. Against its concave lateral border lies the medial wall of the femoral canal. The strong fibrous pectineal ligament extends from the base of the lacunar ligament along the pecten pubis.

**Reflected (Inguinal) Ligament.** The reflected ligament (Figs. 6-27; 6-30) is a triangular, tendinous sheet, 2 or 3 cm wide, extend-

<sup>1</sup>Sir Astley Paston Cooper (1768-1841): An English anatomist and surgeon (London).

**Fig. 6-27.** The aponeurosis of the obliquus externus abdominis and the ligaments of the inguinal region. (Redrawn from Eisler.)

ing from the medial part of the inguinal ring to the linea alba. The fibers arise from the attachment of the inguinal ligament to the pectineal line and course upward and medially, deep to the main aponeurosis of the external oblique, and interlace with the fibers of that aponeurosis in the linea alba. The reflected ligament may be independent, but more often it is fused either with the aponeurosis of the external oblique or with the falx inguinalis, which lies deep to it. Frequently it is entirely lacking.

**Superficial Inguinal Ring.** The superficial inguinal ring (Figs. 6-26 to 6-28) is the opening in the aponeurosis of the external oblique just above and lateral to the pubic crest. This aperture is narrow and triangular, pointing laterally and superiorly in the direction of the fibers of the aponeurosis. The base of the triangular opening is at the crest of the pubis, while the sides form the margins of the aperture in the aponeurosis and are called the crura of the ring. The **lateral (inferior) crus** is the stronger and is formed by the portion of the inguinal ligament that is attached to the pubic tubercle; it is curved and turned under into a narrow sling upon which the spermatic cord rests. The **medial (superior) crus** is thin and flat, and represents merely the part of the aponeurosis next to the opening; its descending fibers are at-

tached to the front of the symphysis pubis. Reinforcing the superficial inguinal ring laterally are arching bands of **intercrural fibers**, which are part of the aponeurosis and course at right angles to the aponeurotic fibers forming the medial and lateral crura (Figs. 6-27; 6-28). The triangular hiatus in the aponeurosis is converted by fascia into an oval ring, 2.5 cm long and 1.25 cm wide. The fascia on the superficial surface of the aponeurosis fuses with the fascia on its deep surface, filling in the angular, lateral portion of the opening. A tubular prolongation of this fascia is continued down into the scrotum, enclosing the spermatic cord and testis in a sheath called the **external spermatic fascia**. The superficial inguinal ring gives passage to the ilioinguinal nerve in both sexes, as well as to the spermatic cord in males or the round ligament of the uterus in females. The ring is larger in men than in women.

**Pectineal Ligament.** The pectineal ligament (of Cooper) is a narrow band of strong aponeurotic fibers that continues laterally from the lacunar ligament along the pectineal line of the pubis (pecten pubis). It is firmly attached to the bone along this line and its medial end is continuous with the lacunar ligament. It diminishes in size gradually toward its lateral extremity at the iliopectineal eminence. It is aponeurotic rather

FIG. 6-28. The superficial inguinal ring.

than fascial in origin, and to it are attached parts of the iliopectineal, pectineal, and transversalis fasciae. It serves well as a site for the attachment of sutures in the repair of femoral hernias and, at times, even of inguinal hernias.

**OBLIQUUS INTERNUS ABDOMINIS.** The internal oblique muscle (Figs. 6-29; 6-30), situated in the lateral and ventral part of the abdominal wall, is of an irregularly quadrilateral form, and is smaller and thinner than the external oblique under which it lies. It arises by fleshy fibers from the lateral half of the inguinal ligament and the nearby iliac fascia, from the anterior two-thirds of the middle lip of the iliac crest, and from the lower portion of the posterior layer of the thoracolumbar fascia near the crest. The posterior fasciculi pass upward and laterally to be inserted into the inferior borders of the cartilages of the last three or four ribs by fleshy digitations which appear to be continuations of the internal intercostal muscles. The remainder of the fasciculi, which arises from the iliac crest, diverges as it spreads

over the side of the abdomen and, in the region of the linea semilunaris, terminates in an aponeurosis that fuses with the aponeuroses of the externus and the transversus at a variable distance from the midline. The fibers of the aponeurosis assist in the formation of the rectus sheath, and in the upper two-thirds of the anterior abdominal wall, some of the aponeurosis passes ventrally and some dorsally to the rectus abdominis muscle. Over the lower one-third of the abdomen, the entire aponeurosis of the internal oblique passes anterior to the rectus muscle, since the posterior part of the rectus sheath is wanting at this level. The fasciculi arising from the inguinal ligament are less compact and of paler color. Descending, they form an arch over the spermatic cord in the male or the round ligament in the female. These muscle fibers terminate in a tendinous sheet, which they share with the others from the transversus muscle. This sheet is not fused with the aponeurosis of the externus, but independently is inserted into the pubis and medial part of the pectineal line, behind

FIG. 6-29. The obliquus internus abdominis muscle.

the lacunar ligament, where it becomes the **conjoined tendon** (inguinal falx).

**Action.** The **obliquus abdominis internus** compresses the abdominal contents, assisting in micturition, defecation, emesis, parturition, and forced expiration. Both sides acting together flex the vertebral column, drawing the costal cartilages downward toward the pubis. One side acting alone bends the vertebral column laterally, rotating it and bringing the shoulder of the opposite side anteriorly.

**Nerves.** The internal oblique is supplied by branches of the **eighth to twelfth intercostal nerves** and by the iliohypogastric and ilioinguinal branches of the **first lumbar nerve**.

**Variations.** Occasionally, tendinous inscriptions to the internal oblique muscle occur from the tips of the tenth or eleventh cartilages or even from the ninth. An additional slip to the ninth cartilage is sometimes found, and separation between iliac and inguinal parts of the internal oblique may occur.

**CREMASTER MUSCLE.** The cremaster (Figs. 6-29; 6-30) is a thin muscular layer whose

fasciculi are separate and spread out over the spermatic cord in a series of loops. It arises from the middle of the inguinal ligament as a continuation of the internal oblique muscle, with some attachments also from the transversus, and is inserted by a small pointed tendon into the tubercle and crest of the pubis and into the front of the sheath of the rectus abdominis. The fasciculi form a compact layer as they lie within the inguinal canal. After passing through the superficial inguinal ring, the muscle fibers form a series of loops, the longest of which extends down as far as the testis, and these are attached to the tunica vaginalis. The intervals between the loops are occupied by fascia, called the **cremasteric fascia**, which is a fused continuation of the fasciae over the deep and superficial surfaces of the internal oblique. The muscular loops and the fascia together form a single layer, which constitutes the middle fascial tunic of the spermatic cord.

**Fig. 6-30.** The cremaster, inguinal falx, and reflected inguinal ligament.

**Action.** The **cremaster** muscle draws the testis up toward the superficial inguinal ring.

**Nerve.** The cremaster muscle is supplied by the genital branch of the **genitofemoral** nerve, which is derived from the **first and second lumbar** nerves.

**TRANSVERSUS ABDOMINIS.** The transversus abdominis muscle (Figs. 6-31; 6-32) derives its name from the direction of its fibers. It is the most internal of the flat muscles of the abdomen, being placed immediately deep to the internal oblique. It arises by fleshy fibers from the lateral third of the inguinal ligament, from the anterior three-fourths of the inner lip of the iliac crest, from the thoracolumbar fascia between the iliac crest and the twelfth rib, and from the inner surface of the cartilages of the last six ribs. The origin from the ribs is by means of digitations, which are separated from similar digitations of the diaphragm by a narrow fibrous raphe. Viewed from the interior of the abdomen, the two muscles appear to be components of a single stratum of muscle (Fig. 6-24). The fasciculi of the transversus, except the most inferior, pass horizontally across the abdominal wall

and terminate in an aponeurosis that fuses with the aponeurosis of the internal oblique. These join the aponeurosis of the opposite side to form the insertion of the muscle into the linea alba. The aponeurosis of the transversus muscle assists in the formation of the sheath of the rectus abdominis as follows: the upper three-quarters of the aponeurosis of the transversus pass entirely posterior to the rectus muscle, and contribute to the formation of its posterior sheath. The lower one-quarter, beyond a curved fibrous border called the **arcuate line**, approximately half way between the umbilicus and the pubis, passes entirely anterior to the rectus abdominis muscle. The fasciculi of the lowest portion of the muscle pass downward and medially and terminate as the **conjoined tendon** along with the lowest fasciculi of the internal oblique. Inferiorly, the muscle presents a free border that forms an arch extending from the lateral part of the inguinal ligament to the pubis, a short distance above the deep inguinal ring and spermatic cord.

**Action.** The **transversus abdominis** constricts the abdomen, compressing the contents and assisting in micturition, defecation, emesis, parturition, and forced expiration.

**Nerves.** The transversus abdominis muscle is supplied by branches of the **seventh to twelfth intercostal** nerves and by the iliohypogastric and ilioinguinal branches of the **first lumbar** nerve.

**Variations.** The transversus abdominis may be more or less fused with the internal oblique or may be absent. The spermatic cord may pierce its lower border. Slender muscle slips may be found from the iliopectineal line to the transversalis fascia, the aponeurosis of the transversus abdominis, or the outer end of the arcuate line.

**Conjoined Tendon** (Inguinal Falx). The conjoined tendon (Figs. 6-29 to 6-32) is the inferior terminal portion of the common aponeurosis of the internal oblique and transversus abdominis muscles. It is inserted into the crest and pecten of the pubis immediately deep to the superficial inguinal ring, giving strength from behind to a potentially weak point in the anterior abdominal wall. There is a wide variation in its width, strength, composition, and degree of union with neighboring aponeurotic and fascial structures. It may be narrow with a high arch, scarcely reaching the lateral part of the superficial inguinal ring, or it may be a broad, strong band, arching close to the in-

Fig. 6-31. The transversus abdominis, rectus abdominis, and pyramidalis.

guinal ligament, and greatly reinforcing the abdominal wall in the region of the ring. In many cases it could be called the conjoined muscle instead of the conjoined tendon because the muscular fasciculi continue almost to the pubis. Frequently it is intimately fused with the reflected inguinal ligament, which lies between it and the aponeurosis of the external oblique. It may be reinforced on its deep surface by a lateral fascial expansion of the lowermost part of the rectus tendon called **Henle's ligament**.<sup>1</sup>

<sup>1</sup>Friedrich Gustav Jacob Henle (1809–1885): A German anatomist and pathologist (Göttingen).

**RECTUS ABDOMINIS.** The rectus abdominis (Figs. 6-31; 6-32) is a long flat muscle that extends along the whole length of the ventral aspect of the abdomen. It is broader but thinner superiorly, and is separated from its fellow of the opposite side by the linea alba. It arises inferiorly by two tendons. The lateral tendon of origin is the larger and it is attached to the crest of the pubis, while the medial tendon interlaces with its fellow of the opposite side and is connected with the ligaments covering the front of the symphysis pubis. The muscle is inserted by three fascicles of unequal size into the cartilages of the fifth, sixth, and seventh ribs. The su-

**FIG. 6-32.** The interfoveolar ligament, ventral aspect. The spermatic cord passes through the deep inguinal ring lateral to the ligament. (Modified from Braune.)

perior fascicle, attached principally to the cartilage of the fifth rib, usually has some fibers of insertion into the ventral extremity of the rib itself. Some fibers are occasionally attached to the costoxiphoid ligaments, and to the side of the xiphoid process.

The rectus abdominis muscle is crossed by fibrous bands, three in number, which are named the **tendinous intersections**. One intersection is usually situated opposite the umbilicus, one at the free extremity of the xiphoid process, and the third about midway between the xiphoid process and the umbilicus. These inscriptions pass transversely or obliquely across the muscle in a zigzag course. They rarely extend completely through its substance and may pass only halfway across it, and they are intimately adherent to the sheath of the muscle anteriorly. Sometimes one or two additional inscriptions, generally incomplete, are present below the umbilicus.

**Action.** The rectus abdominis flexes the vertebral column, particularly the lumbar portion, drawing the sternum toward the pubis. It also tenses the anterior abdominal wall and assists in compressing the abdominal contents.

**Nerves.** The rectus abdominis is innervated by branches of the **seventh to twelfth intercostal nerves**. The seventh supplies the portion above the first tendinous intersection, the eighth innervates the

portion between the first and second intersections, and the ninth the portion between the lower two intersections.

**Variations.** The rectus may insert as high as the fourth or third rib or may be short and fail to reach the fifth. Fibers may spring from the lower part of the linea alba. Both the aponeurotic composition and the position of the arcuate line may vary considerably.

**Sheath of the Rectus Abdominis.** The rectus abdominis is enclosed in a sheath (Figs. 6-29; 6-31; 6-33) that holds it in position but does not restrict its motion during contraction because it is separated from the muscle by a fascial cleft. The sheath is formed by the aponeuroses of the external oblique, internal oblique, and transversus muscles, which preserve their identity in some regions but fuse or interlace in others. At the lateral border of the rectus, the aponeuroses form two membranes, the anterior and posterior lamellae of the sheath.

The aponeurosis of the externus keeps its position anterior to the rectus muscle throughout its entire length, but fuses with the aponeurosis of the internus at a variable distance from the midline (Fig. 6-33, A to C). The line of fusion between the aponeuroses of the external and internal obliques is close to the linea alba at the pubis and below the umbilicus, and gradually angles laterally as

well as superiorly, but remains medial to the lateral border of the rectus. Thus, a surgical incision over the rectus, below the umbilicus, will go through the aponeuroses of the externus and internus as separate layers before it reaches the rectus muscle itself.

The aponeurosis of the internus, above the umbilicus, splits into two layers, one of which passes anterior to the rectus and fuses with the externus as just described (Fig. 6-33, B). The other layer passes posterior to the rectus and fuses with the aponeurosis of the transversus to form the posterior layer of the sheath. Above the costal margin, to which the internus muscle is attached, the costal cartilages and xiphoid process of the sternum take the place of the dorsal layer of the aponeurotic sheath. The posterior layer of the internus aponeurosis, above the costal margin, is attached to the cartilages, while the anterior layer ends abruptly in a fibrous band. Thus, the rectus muscle above the costal margin is covered anteriorly only by the aponeurosis of the external oblique.

The aponeurosis of the transversus, above the umbilicus, passes entirely dorsal to the rectus and fuses with the aponeurosis of the internus as described above (Fig. 6-33, B).

Below the umbilicus the disposition of the aponeuroses is somewhat more complicated and variable. At a variable distance between the pubis and umbilicus, usually about half way, the contribution of the aponeuroses to the posterior layer of the rectus sheath ceases abruptly in a curved, nearly semicircular line, called the **arcuate line** (of Douglas<sup>1</sup>). Below this line the aponeurotic fibers of all three muscles pass anterior to the rectus muscle (Fig. 6-33, C). Between the umbilicus and the arcuate line, the aponeuroses of the internus and transversus fuse and interdigitate, and fiber bundles from both may pass either anterior or posterior to the rectus. Usually a short distance above the arcuate line, the internus terminates its contribution to the posterior lamella and only the aponeurosis of the transversus remains posterior to the muscle. Thus, in the majority of instances, the arcuate line itself is formed by aponeurotic fibers of the transversus alone.

Below the arcuate line the posterior layer of the rectus sheath consists only of trans-

versalis fascia, since the aponeuroses of all three flat abdominal muscles pass anterior to the rectus abdominis. This posterior portion of the sheath is occasionally reinforced by scattered tendinous bundles from the transversus and by thickened laminae of the subserous fascia. In addition to the rectus muscle, the sheath contains the pyramidalis muscle, the superior and inferior epigastric arteries and veins, and branches of the intercostal nerves.

**PYRAMIDALIS MUSCLE.** The pyramidalis is a small triangular muscle, placed at the lower part of the abdomen, in front of the rectus, and contained in the sheath of that muscle (Fig. 6-31). It arises by tendinous fibers from the ventral surface of the pubis and the anterior pubic ligament. The fleshy portion of the muscle extends superiorly, diminishing in size as it ascends, and ends by a pointed extremity which is inserted into the linea alba, midway between the umbilicus and pubis.

**Action.** The pyramidalis muscle tenses the linea alba.

**Nerve.** The pyramidalis is supplied by a branch of the **twelfth thoracic nerve**.

**Variations.** The pyramidalis may vary from 1.5 to 12 cm in length, but it averages between 6 and 7 cm. It is occasionally doubled on one or both sides, and the muscles of the two sides may be unequal in size. The pyramidalis is absent in 10% of bodies, in which case the inferior end of the rectus is proportionately larger.

**Linea Alba.** The linea alba (Fig. 6-26) is the name given to the portion of the anterior abdominal aponeurosis or rectus sheath in the midline. Extending from the xiphoid process to the symphysis pubis, it is formed by an interlacing and fusion of fibers of the aponeuroses of the external oblique, internal oblique, and transversus muscles of both sides. It is broader above where the recti are separated from each other by a considerable interval. A surgical incision above the umbilicus in the midline will go through the linea as a single aponeurotic layer. It is narrower below, where the recti are more closely placed. A surgical incision in the midline below the umbilicus usually penetrates the anterior and posterior lamellae of the rectus sheath as individual layers. The inferior end of the linea alba has a double attachment. The superficial one passes in front of the medial heads of the recti to the

<sup>1</sup>James Douglas (1675-1742): An Irish physician and anatomist, who worked in London.

**Fig. 6-33.** Diagrams of cross sections of the anterior abdominal wall, showing the formation of the sheath of the rectus abdominis muscle above the costal margin, A, just above the umbilicus, B, and below the arcuate line, C.

symphysis pubis. The deeper attachment spreads out into a triangular sheet dorsal to the recti, attaches to the posterior lip of the crest of the pubis, and is named the **adminiculum lineae albae**. The **umbilicus**, which is an aperture for the passage of the umbilical vessels, the urachus, and during the first trimester, the vitelline duct in the fetus, is closed in the adult and presents a hard fibrous ring or plate of scar tissue within the linea alba.

**Arcuate Line.** The arcuate line (semicircular line of Douglas) is a curved, upwardly convex, tendinous band in the posterior lamella of the rectus sheath below the umbilicus (Fig. 6-32). It marks the inferior limit of the aponeurotic portion of the posterior lamella, the latter being composed of only transversalis fascia inferior to the line. Arching from the lateral border of the sheath, the arcuate line may be found 4 to 13 cm, average 8 cm, from the pubis. From each side, the arcuate line terminates at the linea alba, although occasionally as far down as the pubic crest. Its tendinous bundles are usually derived from the aponeurosis of the transversus abdominis, but may be from the internal oblique or from an interlacing of fibers from both the transversus and the internus. A secondary line may be found

superior to the primary one, especially in those instances where the primary line is formed by the transversus. In these cases the secondary line is formed by the aponeurotic fibers of the internal oblique.

**Linea Semilunaris.** The linea semilunaris (Fig. 6-26), a slightly curved line on the anterior abdominal wall, courses approximately parallel to the midline and lies about half way between the linea alba and the side of the body. It marks the lateral border of the rectus abdominis muscle, and can be seen as a shallow groove in the living subject when that muscle is tensed. The abdominal wall is thin along this line, particularly its inferior part, where it is composed only of the aponeuroses of the oblique and transversus muscles and their fasciae. At its superior end the linea semilunaris is thicker where the muscular fasciculi of the transversus extend deep to the rectus for a variable distance.

**Group Actions.** If pelvis and thorax are fixed, the abdominal muscles, assisted by the descent of the diaphragm, compress the abdominal viscera by constricting the cavity of the abdomen. By these means assistance is given in expelling the feces from the rectum, the urine from the bladder, the fetus from the uterus, and the contents of the stomach in vomiting.

If the pelvis and vertebral column are fixed, these

muscles compress the inferior part of the thorax, significantly assisting expiration. If the pelvis alone is fixed, the thorax is bent directly anteriorly when the muscles of both sides act. When the muscles of only one side contract, the trunk is bent toward that side and rotated toward the opposite side.

If the thorax is fixed, the muscles acting together draw the pelvis upward as in climbing. Acting singly, they draw the pelvis upward and bend the vertebral column to one side or the other. The recti, acting from below, depress the thorax and consequently flex the vertebral column. When acting from above, the recti flex the pelvis upon the vertebral column. The abdominal muscles are the **flexors of the vertebral column**, an important action that is frequently overlooked.

**TRANSVERSALIS FASCIA.** The internal investing layer of deep fascia that lines the entire wall of the abdomen is called the **transversalis fascia** (Fig. 6-18). It may be defined even to include the pelvic portion of this internal layer, although more frequently, within the pelvis, this layer is called the **endopelvic fascia**. Formerly, the name was applied only to the deep fascia covering the internal surface of the transversus abdominis muscle, but because this muscle occupies a large proportion of the surface of the abdominal cavity, the name has gradually become adopted for the entire internal sheet. Various parts of it are still referred to by more specific designations such as the *iliac*, *psoas*, or *obturator fascia*, used for the portions covering these muscles. This internal fascia is of surgical interest, and in different areas it covers muscles, aponeuroses, bones, and ligaments. The transversalis fascia completely encases the abdominal cavity, but it may be thin and adherent in one place or thickened and independent in another. It gives rise to specialized structures such as tubular investments, and from it are derived certain components of important extra-abdominal fasciae. It is a gray, felt-like membrane, sometimes transparent, sometimes thickened into strong bands, but seldom aponeurotic in appearance and, except in obese individuals, contains no fat. Between this membrane and the peritoneum there is a layer of subserous fascia that may contain fat.

A definitive part of the transversalis fascia, that covering the internal surface of the muscular portion of the transversus muscle, is readily identifiable at dissection. Over the aponeurosis of this muscle, however, it is

thin and so closely adherent that only with difficulty can it be dissected free. Extending *superiorly* from the muscular portion of the transversus, the transversalis fascia continues onto the undersurface of the diaphragm, covering its entire abdominal dimension. It is thin and adherent over the diaphragmatic muscular portion as well as over the central tendon. *Anteriorly*, the fascia over the transversus aponeurosis of one side is continuous across the midline with that of the other side. *Posteriorly*, as it leaves the muscular fasciculi of the transversus, it continues for a short distance over the aponeurosis of origin of this muscle and then covers the abdominal surface of the quadratus lumborum and the psoas muscles. From the psoas it extends over the crura of the diaphragm and over the bodies and discs of the lumbar vertebrae, and is then continuous with the fascia over the psoas of the other side. As the dorsal origin of the diaphragm crosses the quadratus lumborum and psoas, the fascia is thickened into the strong, fibrous medial and lateral arcuate ligaments. *Inferiorly*, from the muscular portions of the transversus and quadratus lumborum, the fascia is attached to bone along the crest of the ilium and continues into the greater pelvis on the surface of the iliacus muscle. From the iliacus and psoas muscles, the transversalis fascia is continuous with the endopelvic fascia (described in the section dealing with the muscles of that region).

The fascia on the internal surface of the anterior abdominal wall *below the umbilicus* requires a more detailed description. In a medial direction from the muscular fasciculi of the transversus, the transversalis fascia, below the umbilicus, continues on the surface of the aponeurosis toward the midline. The portion *below the arcuate line*, however, splits at the lateral border of the rectus into two sheets. The thin anterior sheet continues on the aponeurosis of the transversus, and passes with it anterior to the rectus. A thick posterior sheet forms the posterior lamina of the rectus sheath, serving to separate the lower portion of the rectus muscle from abdominal viscera. Lateral to the lower part of the rectus, the transversalis fascia continues downward on the transversus aponeurosis to its lowest limit. At this site it covers the inner surface of the conjoined tendon (inguinal falx), and passing over the free border of the transverse

aponeurosis, it forms an arch extending from the crest of the pubic bone to the lateral part of the inguinal ligament. The fascial membranes on both the deep and superficial surfaces of the transversus fuse into a single sheet at this free border, providing reinforcement of the transversalis fascia as it bridges the interval between the lower arched border of the transversus muscle and the inguinal ligament (Fig. 6-34).

At a point just above the middle of the inguinal ligament, a tubular prolongation of this reinforced fascia is carried outward on the ductus deferens and testicular vessels as they leave the abdominal cavity. This tubular investment is the inner coat of the spermatic cord and testis and is known as the **internal spermatic fascia** (Fig. 6-34). The ductus deferens (or round ligament) and vessels leave the abdominal cavity at a point which is called the **deep** (abdominal or internal) **inguinal ring**, and they follow an oblique course through the abdominal wall in a tunnel called the **inguinal canal**. The lateral part of this canal, that is, before it has begun to penetrate the internal oblique muscle, has transversalis fascia forming its posterior wall. The fascia is loosely attached to the inguinal ligament and has two thickenings near the ring, one extending cranialward

called the **interfoveolar ligament**, one extending caudalward called the **deep crural arch**.

**Interfoveolar Ligament (of Hesselbach<sup>1</sup>).** The interfoveolar ligament (Fig. 6-32) is a thickening in the transversalis fascia which forms a crescentic medial boundary for the deep inguinal ring. Connected above to the transversus muscle and below to the inguinal ligament, it may be poorly defined or it may be a strong band whose fibers fan out medially as it follows the upward course of the deep inferior epigastric artery. It forms a slight ridge, usually palpable from the interior of the abdominal cavity, which extends upward from the middle of the inguinal ligament, dividing the shallow fossa above the ligament into **medial** and **lateral inguinal fovea**. The deep inguinal ring, through which the ductus deferens or round ligament of the uterus leaves the abdominal cavity, is in the lateral fovea, and it is here that the sac of an indirect inguinal hernia penetrates the abdominal wall. In the medial fovea, a triangular area is marked out by the inguinal ligament, the lateral boundary of the rectus abdominis, and the inferior deep

<sup>1</sup>Franz Kaspar Hesselbach (1759-1816): A German surgeon (Würzburg).

FIG. 6-34. The deep, internal, or abdominal inguinal ring.

epigastric artery. This is the **inguinal triangle** (of Hesselbach) and a **direct inguinal hernia** penetrates through it.

**Deep Crural Arch.** The deep crural arch (sometimes called the iliopubic tract) is a downward extension of the transversalis fascia from the region of the internal inguinal ring. It arches across the external iliac vessels as they pass beneath the inguinal ligament and marks the transition from transversalis fascia to femoral sheath (Clark and Hashimoto, 1946). Laterally, it is attached to the iliac fascia where the latter gives origin to the inferior fibers of the transversus muscle. Medially, it follows the downward curve of the lacunar ligament. It may be a strong band or it may be poorly defined and appear to be merely the proximal part of the femoral sheath.

**Deep Inguinal Ring.** The deep inguinal ring (abdominal or internal inguinal ring) is that interruption in the transversalis fascia where the spermatic cord (round ligament in the female) penetrates the anterior abdominal wall (Fig. 6-33), carrying with it a sleeve-like investment of the transversalis fascia called the internal spermatic fascia. It is situated 1.25 cm above the inguinal ligament, midway between the anterior superior iliac spine and the symphysis pubis. It is oval in form, the long axis of which is vertical. It varies in size, being larger in males than in females, and fits rather closely about the penetrating structures, unless the ring has been distended by the sac of an indirect inguinal hernia. It is bounded, superiorly, by the arched inferior margin of the transversus abdominis; medially, by the interfoveolar ligament accompanying the inferior deep epigastric vessels; and inferiorly, by the deep crural arch.

**Inguinal Canal.** The inguinal canal is the tunnel in the lower anterior abdominal wall through which the spermatic cord (round ligament in the female), as well as the ilioinguinal nerve, pass. Its internal or lateral end is at the deep inguinal ring, and its external or medial end is at the superficial inguinal ring. The canal is about 4 cm long and takes an oblique course parallel with and a little above the inguinal ligament. It is bounded superficially by the skin, subcutaneous fascia, aponeurosis of the external oblique and, over its lateral third, by the internal oblique. The canal is bounded deeply from its medial to lateral ends by the reflected inguinal ligament, the inguinal falx,

the transversalis fascia, the subserous fascia, and the peritoneum. Proximally are found the arched fibers of the internal oblique and transversus, and distally are located the inguinal ligament and, at its medial end, the lacunar ligament. Through the canal pass the spermatic cord (or round ligament), the ilioinguinal nerve, the testicular vessels, and the cremaster muscle.

**SUBSEROUS FASCIA.** Intervening between the transversalis fascia and the peritoneum is fibroelastic connective tissue that supports the peritoneum. This subserous fascia, also referred to as subperitoneal fascia or extra-peritoneal connective tissue, resembles the subcutaneous superficial fascia in that it supports a free surface epithelial layer. It commonly contains adipose tissue in varying thicknesses, and it is frequently separated from the transversalis fascia by a fascial cleft. Not only does the subserous fascia have a parietal portion supporting the peritoneum of the abdominal wall, but it also has a visceral portion which continues over the viscera at the peritoneal reflections and accompanies the blood vessels into the mesenteries. The subserous fascia has localized thickenings and accumulations of fat that are associated with the particular requirements of the different regions; these are described in sections dealing with the viscera. The subserous fascia in the pelvis is uninterruptedly continuous with that of the abdomen, and will be described with the pelvic viscera.

### **Posterior Muscles of the Abdomen**

Psoas major  
Psoas minor  
Iliacus  
Quadratus lumborum

The psoas major, the psoas minor, and the iliacus, with the fasciae covering them, will be described with the muscles of the lower limb.

**FASCIA COVERING THE QUADRATUS LUMBORUM.** The transversalis (internal investing) fascia covers the lateral portion of the quadratus lumborum on its ventral surface (Fig. 6-18). Since the medial portion of the muscle is overlapped by the psoas muscles, the fascia continues medially between the muscles and is attached to the bases of the transverse processes of the lumbar vertebrae. Its superior portion is thickened into a

strong band, called the lateral arcuate ligament (Fig. 6-25), which is attached to the transverse process of the first lumbar vertebra and the apex and inferior border of the last rib. Inferiorly, the fascia is attached to the crest of the ilium, and is then continuous with the iliac fascia. At the lateral border of the quadratus lumborum, the fascia fuses with the combined fascia and aponeurosis of origin of the transversus muscle. The latter, extending medially from this point of fusion, covers the dorsal surface of the quadratus. The more medial portion of this aponeurotic sheet lies between the quadratus lumborum and the erector spinae and is the anterior layer of the thoracodorsal fascia (Fig. 6-18).

**QUADRATUS LUMBORUM.** The quadratus lumborum (Figs. 6-18; 6-19; 6-25) is irregularly quadrilateral in shape, but it is broader inferiorly. It arises below by aponeurotic fibers from the iliolumbar ligament and for about 5 cm along the adjacent portion of the iliac crest. It is inserted above into the medial one-half of the inferior border of the last rib, and by four small tendons into the apices of the transverse processes of the first four lumbar vertebrae. Occasionally a second portion of this muscle is found anterior to the preceding. When present, it arises from the superior borders of the transverse processes of the last three or four lumbar vertebrae, and is inserted into the inferior margin of the last rib. Anterior to the quadratus lumborum are the colon, the kidney, the psoas major and minor, and the diaphragm. Between the muscle and the transversalis fascia are found the twelfth thoracic, ilioinguinal, and iliohypogastric nerves.

**Action.** When the pelvis is fixed, the **quadratus lumborum** laterally flexes the lumbar vertebral column toward the same side. It also fixes the twelfth rib during deep inspiration, thereby preventing its elevation by the diaphragm. If both muscles act together, they help extend the lumbar vertebral column.

**Nerves.** The quadratus lumborum is innervated by the **twelfth thoracic and the upper three or four lumbar nerves**.

## MUSCLES AND FASCIAE OF THE PELVIS

The muscles within the pelvis may be divided into two groups. The first group consists of the true pelvic muscles.

Levator ani  
Coccygeus

The second group consists of the muscles of the lower limb. These originate within the pelvis and thus form part of the pelvic wall.

Obturator internus  
Piriformis

The muscles of the second group will be described later with the muscles of the lower limb, but their fasciae will be considered in this section because they form an important part of the pelvic fascia.

**PELVIC DIAPHRAGM.** The pelvic diaphragm (Figs. 6-36; 6-39) is composed of the levator ani and coccygeus muscles together with the fasciae covering their superior (internal) and inferior (external) surfaces. It stretches across the pelvic cavity like a hammock. It forms the lowest portion of the body wall, closing the abdominopelvic cavity below, restraining the abdominal contents, and giving support to the pelvic viscera. It is pierced by the anal canal, the urethra, and the vagina, and is reinforced in the perineum by the special muscles and fasciae associated with these structures. The pelvic diaphragm and the structures of the perineum are intimately associated both structurally and functionally, and an accurate knowledge of one cannot be obtained without study of the other.

**LEVATOR ANI MUSCLE.** The levator ani is a broad, thin muscle attached to the internal surface of the pelvis (Fig. 6-35). The muscles of the two sides are separated from each other anteriorly, but are inserted into a raphe posteriorly. They function as a single sheet across the midline, forming the principal part of the pelvic diaphragm. It arises, anteriorly, from the inner surface of the superior ramus of the pubis lateral to the symphysis, and posteriorly, from the inner surface of the spine of the ischium. Between these two points the muscle arises from the **tendinous arch of the levator ani**. This arch is a thickened band of the obturator fascia attached posteriorly to the spine of the ischium and anteriorly to the pubic bone at the ventral margin of the obturator membrane. From their origin the muscle fascicles sweep downward and medially in the floor of the pelvis to be inserted into the side of the last two segments of the coccyx, the anococcygeal raphe, the external anal sphincter, and the central tendinous point of the perineum. The **anococcygeal raphe** is a narrow fibrous band extending from the

coccyx to the posterior margin of the anus where the muscles of the two sides join at the midline. The levator ani consists of two principal parts, usually separated by a triangular gap and generally more distinct in lower mammals than in man, the pubococcygeus and the iliococcygeus.

The **pubococcygeus** arises from the dorsal surface of the pubis along an oblique line extending from the lower part of the symphysis to the obturator canal. The muscular fasciculi pass posteriorly, more or less parallel with the midline, and terminate by joining the fibers from the other side. The lateral margin of the pubococcygeus may be separated from the iliococcygeus by a narrow interval, or it may be overlapped by the latter muscle. Its medial margin is separated from the muscle of the other side by an interval known as the genital hiatus, which allows the passage of the urethra, vagina, and rectum. The most anterior fasciculi, which are also the most medial, pass behind the

prostate in males and insert into the central tendinous point just in front of the anus and are called the **levator prostatae**. In females a similar muscular fascicle passes along the sides of the vagina to insert behind the vagina into the central tendinous point of the perineum. This constitutes an important sphincter of the vagina, the **pubovaginalis**. The majority of the fasciculi of the pubococcygeus pass horizontally backward beside the anal canal. The more superficial ones join the anococcygeal raphe, while the deeper ones join the muscle of the other side to form a U-shaped loop or sling around the rectum called the **puborectalis**.

The **iliococcygeus** arises from the tendinous arch of the levator ani muscle and the spine of the ischium, and inserts into the last two segments of the coccyx and the anococcygeal raphe. Its fasciculi pass medially as well as inferiorly, which helps to distinguish them from the fascicles of the pubococcygeus.

**Fig. 6-35.** Interior of the female pelvis in a sagittal section, showing the muscles of the left lateral wall, the obturator fascia, and the tendinous arch of the levator ani muscle.

**Action.** The levator ani supports and slightly raises the pelvic floor, resisting increased intra-abdominal pressure, as during forced expiration. The pubococcygeus draws the lower end of the rectum toward the pubis and constricts it as well as the vagina.

**Nerves.** The levator ani is supplied by branches of the pudendal plexus, containing fibers from the fourth and sometimes also the third or fifth sacral nerves.

**Variations.** The degree of distinctness of the pubococcygeus and iliococcygeus varies, and the latter may be replaced by fibrous tissue.

**THE COCCYGEUS.** The coccygeus (Fig. 6-35) is located posterior to the levator ani but contiguous with it and on the same plane. It is a triangular sheet of muscular and tendinous fibers, arising by its apex from the spine of the ischium and sacrospinous ligament, and inserted by its base into the margin of the coccyx and into the side of the last piece of the sacrum. It assists the levator ani and piriformis in closing the posterior part of the pelvic outlet. By position it could be considered the "ischiococcygeus" in continuity with the pubo- and iliococcygeus portions of the levator ani.

**Action.** The coccygeus draws the coccyx forward after it has been pushed backward during parturition or defecation. It also supports the pelvic floor against intra-abdominal pressure.

**Nerves.** The coccygeus is supplied by branches of the pudendal plexus that contain fibers from the fourth and fifth sacral nerves.

**Variations.** The iliosacralis is an occasional band of muscle, ventral to the coccygeus, attached to the iliopectineal line and the lateral border of the sacrum. The **sacrococcygeus ventralis** is an occasional muscular or tendinous slip from the anterior surface of the lower sacral vertebrae to the coccyx. The **sacrococcygeus dorsalis** is an inconstant muscular slip that extends from the dorsal aspect of the sacrum to the coccyx.

**PELVIC FASCIA.** This internal investing layer of fascia covers the levator ani and coccygeus and the intrapelvic portions of the obturator internus and piriformis muscles. It is the fascia lining the pelvis that is comparable to the transversalis fascia of the abdomen and is directly continuous with the latter over the brim of the lesser pelvis, where it is attached to or fused with the periosteum of the symphysis and superior ramus of the pubis, the ilium along the arcuate line, and the promontory of the sacrum. From

these attachments it sweeps downward and across the midline, attaching to the ano-coccygeal raphe dorsally and blending with the fasciae of the anal canal and urogenital structures ventrally. Although it is a continuous sheet, for convenience of description it is divided into (1) piriformis fascia, (2) obturator fascia, and (3) superior fascia of the pelvic diaphragm (supra-anal fascia).

The **piriformis fascia** is very thin and is attached to the anterior surface of the sacrum and the sides of the greater sciatic foramen. It is prolonged outward through that foramen, joins the fascia on the external surface of the muscle at its distal border, and, becoming extrapelvic, forms part of the deep gluteal fascia. At its sacral attachment around the margins of the anterior sacral foramina, it ensheathes the nerves emerging from these foramina. Hence the sacral nerves are frequently described as lying behind this fascia. The internal iliac vessels and their branches, on the other hand, lie in the extraperitoneal tissue in front of the fascia, and their branches to the gluteal region emerge in special sheaths of this tissue, proximal and distal to the piriformis muscle.

The **obturator fascia** covers the obturator internus muscle and is partly intrapelvic and partly extrapelvic (Figs. 6-35; 6-36; 6-39). The intrapelvic portion has incorporated in it the aponeurosis of origin of the levator ani. It is as if the levator had at one time been attached to the pelvic brim above the obturator (a condition found in lower primates), but had slipped downward for a variable distance, usually about half the length of the muscle. At this site the origin of the levator is visible as a thickened band called the **tendinous arch of the levator ani muscle** (Fig. 6-36). Posteriorly, the arch always ends by attaching to the spine of the ischium. Anteriorly, although more variable, the arch usually attaches to the anterior margin of the obturator membrane or the pubic bone medial to it. Since the levator closes the aperture of the pelvis, the arch marks the boundary between the intra- and extrapelvic portions of the obturator fascia. The intrapelvic portion usually is not aponeurotic in appearance and may be quite thin except at the tendinous arch. Anteriorly, the obturator fascia is attached to the superior border of the obturator membrane or the pubic bone just in front of the obturator canal. It con-

Fig. 6-36. Fasciae of pelvis and anal region of perineum. Diagram of frontal section.

tributes a tubular investment for the obturator nerve and vessels as they leave the pelvis through that canal. Its attachment to the bone gradually angles cranialward from the obturator membrane until it reaches the arcuate line near the sacroiliac articulation. Posteriorly, it is attached to the margin of the greater sciatic notch down to the spine of the ischium. At the tendinous arch of the levator ani, the obturator fascia splits into three sheets, the outer one continues as the extrapelvic (perineal) obturator fascia, the other two cover the superior (intrapelvic) and inferior (perineal) surfaces of the pelvic diaphragm. The extrapelvic, perineal portion of the obturator fascia follows the muscle downward into the ischiorectal fossa and will be described with the perineum.

The **superior fascia of the pelvic diaphragm** (supra-anal fascia) covers the superior (intrapelvic or internal) surface of the levator ani and coccygeus muscles (Figs. 6-36; 6-39). Anteriorly, above the pubococcygeus part of the levator, it is attached to the pubic bone. Laterally, above the iliococcygeus, it is continuous with the intrapelvic obturator fascia at the tendinous arch of the levator ani muscle. Posteriorly, it covers the coccygeus and becomes continuous with the fascia of the piriformis. Behind the rectum, the fascia of each side is continuous across the midline over the anococcygeal raphe. In front of the rectum, in the region of

the genital hiatus where the medial borders of the pubococcygei of the two sides do not meet, the superior fascia of the pelvic diaphragm joins the inferior fascia of the pelvic diaphragm to assist in the formation of the deep layer of the urogenital diaphragm.

**SUBSEROUS FASCIA.** The subserous fascia (Figs. 6-36; 6-37; 6-39), continuous with the subserous fascia of the abdomen, not only covers the parietal wall of the pelvis and the viscera, but also acts as a padding tissue for the viscera in the lower part of the pelvis. It forms important fascial ligaments and folds that extend from the pelvic wall to assist in the support of the pelvic viscera. A thickened band of subserous fascia, the **tendinous arch of the pelvic fascia** on the inner surface of the superior fascia of the pelvic diaphragm (Figs. 6-36; 6-38), marks the site of attachment of the lateral ligament of the bladder. Other supporting subserous fascial folds of this type are described in the chapter dealing with the pelvic viscera.

#### MUSCLES AND FASCIAE OF THE PERINEUM

The perineum is a diamond-shaped region that lies immediately beneath the outlet of the pelvis. Bony structures form its boundaries as follows: anterior, the pubic arch and the arcuate ligament of the pubis; posterior, the tip of the coccyx; and on each side, the

FIG. 6-37. Diagram of fasciae of pelvis and perineum in median sagittal section.

inferior rami of the pubis and ischium, and the sacrotuberous ligament. The perineum is limited on the surface of the body by the external genitalia ventrally, by the buttocks dorsally, and laterally by the medial side of the thigh. A line drawn transversely between the ischial tuberosities divides the diamond-shaped region into two portions or triangular parts. The posterior contains the termination of the anal canal and is known as the **anal region or triangle**, while the anterior, which contains the external urogenital organs, is termed the **urogenital region or triangle**.

### Perineal Fasciae

**SUPERFICIAL FASCIA.** The superficial fascia of the perineum is divisible into two layers, superficial and deep, which are similar to and continuous with the corresponding layers of the anterior abdominal wall (Figs. 6-37; 6-38). The deep layer is called the fascia of Colles instead of Scarpa. The superficial layer, corresponding to Camper's fascia,

usually is not specifically named, although it has been called Cruveilhier's fascia.<sup>1</sup>

**Superficial Layer (of Superficial Fascia).** The most superficial layer of fascia in the anterior part of the perineum, that is, over the urogenital region, contains a considerable amount of adipose tissue and is likely to be irregularly laminated. In the groove between the scrotum or labium majus and the thigh, it is directly continuous with the corresponding layer on the anterior abdominal wall. More medially, it is combined with the deep layer into the dartos tunic of the scrotum in the male, while in the female, it forms the greater part of the labium majus. Laterally, it is continuous with the superficial layer of the thigh, and posteriorly, it becomes the most superficial layer of fascia in the anal region.

The superficial layer in the anal region is greatly thickened into a mass of fat, which occupies the ischiorectal fossa. It is continu-

<sup>1</sup>Jean Cruveilhier (1791-1874): A French anatomist and pathologist (Paris).

FIG. 6-38. Fasciae of perineum. Dissection of superficial layers.

ous posteriorly with the superficial fascia of the gluteal region and posterior thigh. Covering the ischial tuberosities, the fibrous tissue is increased in amount, forming a tough pad.

The **ischiorectal fossa** (Fig. 6-38) is somewhat prismatic and wedge-shaped, with its base at the surface of the perineum and its apex deeply placed in the perineum at the line of meeting of the levator ani and obturator internus muscles. The fossa is bounded medially by the inferior fascia of the pelvic diaphragm covering the levator ani and external anal sphincter; laterally, by the obturator fascia over the extrapelvic portion of the obturator internus, and by the tuberosity of the ischium; anteriorly, by the posterior borders of the transversus perinei superficialis and profundus; and posteriorly, by the fascia over the gluteus maximus and the sac-

rotuberous ligament. The superficial boundary is the skin, and the fossa is occupied by a mass of adipose tissue belonging to the most superficial layer of fascia. The superficial and deep layers of the superficial fascia are not separable in the fossa and both are securely attached to the deep fascia covering the entire inner surface of the fossa. The dorsal portion of the transversus perinei profundus is separated from the levator ani for a short distance, so that the ischiorectal fossa has an **anterior recess** which extends beneath the posterior border of the transversus muscles. The adipose tissue within the fossa is traversed by fibrous bands and incomplete septa. The ischiorectal fossa is crossed transversely from lateral to medial by the inferior rectal vessels and nerves. In the posterior part of the fossa are the peri-

neal and perforating cutaneous branches of the pudendal plexus, while from the anterior part of the fossa emerge the posterior scrotal (or labial) vessels and nerves. The internal pudendal vessels and pudendal nerve achieve the fossa by means of the **pudendal canal** (of Alcock<sup>1</sup>), which passes deep to the obturator fascia in a special reduplication of that fascia on the lateral wall of the fascia.

**Deep Layer of Superficial Fascia (Colles' Fascia).** In the urogenital region, but not in the anal region, the deep layer of superficial fascia is a distinctive structure (Figs. 6-36 to 6-39). It is a strong membrane but does not have the white glistening appearance of an aponeurosis. Instead, it has a slightly yellow color due to its content of elastic fibers, and it is smooth in texture, its fibrous nature not being detectable with the naked eye. This characteristic texture frequently is of assistance in differentiating it from the deep fascia in the region. Anteriorly, it is directly continuous with the deep layer of superficial abdominal fascia (Scarpa's fascia) in the groove between the scrotum or labium majus and thigh. More medially, it joins the superficial layer in the formation of the

dartos tunic of the scrotum (Fig. 6-37). In the midline, the deep layer of superficial fascia is attached to the superficial layer along the raphe and continues ventrally into the **scrotal septum**, which divides that sac into two cavities. Laterally, it is firmly adherent to the medial surface of the thigh along the ischiopubic ramus at the origin of the adductor muscles. In the anterior part of this area, it is continuous with the fascia cribrosa which covers the saphenous opening. Posteriorly, it dips inward toward the ischiorectal fossa around the posterior border of the transversus perinei superficialis and becomes firmly attached to the deep fascia along the posterior border of the transversus perinei profundus. It is attached also, with all the other layers, to the central tendinous point of the perineum.

A fascial cleft, *not recognized in most other accounts of the perineal fascia*, has been described between Colles' fascia and the external perineal fascia (a deep fascial layer also not usually recognized), overlying the bulbocavernosus, ischiocavernosus, and the transverse perinei superficialis muscles. This **superficial perineal cleft** is thought by some to be continuous with the cleft deep to Scarpa's fascia on the anterior abdominal wall, but it is closed off laterally and posteriorly by the attachments described above.

<sup>1</sup>Benjamin Alcock (1801-?): An Irish anatomist (Cork, then America).

FIG. 6-39. Fasciae of pelvis and urogenital region of perineum. Diagram of frontal section.

In the anal region, the deep layer of the superficial fascia is adherent both to the superficial layer and to the deep fascia. Although not easily dissected in this region, its attachment to the posterior border of the transversus perinei profundus, mentioned previously, continues deeply into the ischio-rectal fossa in close apposition to the inferior fascia of the pelvic diaphragm covering the inferior surface of the levator ani muscle. At the origin of this muscle, the deep layer of superficial fascia folds back sharply over the extrapelvic portion of the obturator fascia. Posteriorly, it leaves the ischio-rectal fossa along the border of the gluteal region and posterior thigh.

**DEEP FASCIAE.** The deep fasciae of the perineum consist of the obturator fascia and the inferior fascia of the pelvic diaphragm in the anal region, and in the urogenital region, of the superior and inferior fascial layers of the urogenital diaphragm, along with the external perineal fascial layer (frequently not cited in other descriptions). The phenomena of splitting, fusion, and cleavage are prominent features of fascia in this region. The clinical interest and importance of these fasciae have made them the subject of numerous treatises in which the various parts are frequently segregated and given special names. In the following description these parts will be considered individually, but an attempt will be made to correlate the diverse terminology into a consistent description.

The **obturator fascia** (perineal part) covers the extrapelvic portion of the obturator internus muscle and forms the lateral wall of the ischio-rectal fossa. Superiorly, it meets the inferior fascia of the pelvic diaphragm at a sharp angle in the deepest part of the fossa. Its inferior portion, extending from the lesser sciatic foramen to the ischial tuberosity, is thickened and splits to enclose the pudendal nerve and internal pudendal vessels in a fibrous tunnel called the **pudendal canal** (of Alcock). Anteriorly, it is attached to the ischiopubic ramus, and the fibrous sheath of the pudendal canal merges with the inferior fascia of the urogenital diaphragm (and perhaps with the external perineal fascia) where branches of the nerve and vessels enter the superficial and deep perineal spaces or compartments.

The **inferior fascia of the pelvic diaphragm**, also known as the infra-anal fascia, covers the inferior or perineal (external, or

superficial) surface of the levator ani and coccygeus muscles (Figs. 6-36 to 6-39). It adheres to the muscle throughout. Superiorly, the portion of this fascia subjacent to the iliococcygeus is continuous with the extra-pelvic obturator fascia at the tendinous arch of the levator ani. The portion underlying the pubococcygeus is attached to the ischiopubic ramus and the pubic bone at the origin of the muscle. Between the medial borders of the two pubococcygei, the infra-anal fascia joins the supra-anal fascia to form a thick sheet in the genital hiatus. Behind the rectum, the inferior fascia of the pelvic diaphragm is continuous from side to side over the anococcygeal raphe where it is firmly attached. More laterally, it bridges the slight interval between the levator ani and coccygeus, and then binds the latter muscle to the inferior edge of the sacrospinous ligament. From this ligament, it passes outward from the ischio-rectal fossa along the overhanging distal border of the gluteus maximus, becoming continuous with the gluteal fascia. Near the anus, it invests the external anal sphincter, and just anterior to the anus, it is firmly attached to the other perineal layers at the central tendinous point.

If the infra-anal fascia is traced anteriorly from the ischio-rectal fossa, it will be seen to split into two sheets at a transverse line connecting the anterior extremities of the ischial tuberosities (three sheets if the external perineal fascia is considered). The deepest of these continues on the surface of the levator ani, and lying between this muscle and the transversus perinei profundus, it is called the **superior layer of the urogenital diaphragm**. Another of the fascial sheets covers the superficial surface of the transversus profundus and is called the **inferior layer of the urogenital diaphragm**. If the external perineal fascia is considered a true fascial plane, it would be the most superficial of these deep fascial layers in the urogenital region which split from the inferior fascia of the pelvic diaphragm in the mid-perineum.

**UROGENITAL DIAPHRAGM.** The transversus perinei profundus muscle is covered superiorly (internally) and inferiorly (externally) by fascial membranes that are called, respectively, the superior and inferior layers of the urogenital diaphragm (Fig. 6-39). The transversus perinei profundus muscle and the two fascial layers taken together constitute the **urogenital diaphragm**. The urogeni-

tal diaphragm is synonymous with the **deep perineal compartment** (pouch or space) and its contents, which will be described. The urogenital diaphragm, as it has just been defined, is assisted in its role as a supporting structure by the portion of the levator ani over which it lies and by the superficial perineal muscles and their fasciae.

The **genital hiatus** is the interval in the midline between the medial borders of the two pubococcygeus portions of the levator ani muscle. It is through this hiatus that the urethra passes in both sexes and the vagina in the female. The fibrous tissue composing the region of the genital hiatus is derived from the superior and inferior fasciae of the pelvic diaphragm and the superior layer of the urogenital diaphragm.

The **superior fascia of the urogenital diaphragm** (also called deep or internal fascia) is a flat, triangular membrane stretching across the interval between the ischiopubic rami (Figs. 6-37; 6-39). It lies between the transversus perinei profundus and the pubococcygeus portions of the levator ani and represents the fused fascial membranes of both these muscles. It represents also, in the genital hiatus between the medial borders of the two pubococcygei, a fusion with still a third membrane, the superior fascia of the pelvic diaphragm. It is securely attached to the symphysis pubis anteriorly and joins the other perineal layers at the central tendinous point posteriorly. Laterally, it is attached to the medial borders of the ischiopubic rami, and there it is continuous with the obturator fascia. The middle portion of the fascia, which occupies the genital hiatus, is thickened to fill in the gap between the two pubococcygei and binds their medial borders together. At this site the fascia is pierced by the urethra and vagina, blending with their walls as they pass through. The prostate gland rests on the pelvic surface of the fascia in the male, and the connective tissue of the inferior portion of the prostatic capsule also intimately blends with the fascia. The attachment of the fascia to the pubic bone and its blending with the glandular capsule make the anterior part of the fascia a true **ligament of the prostate**. The tissue attachments may form three strands, a **middle puboprostatic ligament** to the symphysis and two **lateral puboprostatic ligaments**, one to each pubic bone, at the sites where the anterior ends of the tendinous arches of the

levator ani muscles are attached. At the posterior border of the deep transversus, the fascia is fused with the superficial layer of the urogenital diaphragm, closing the deep perineal compartment.

The **inferior fascia of the urogenital diaphragm** (also called superficial or external fascia) is a flat, triangular membranous sheet which, like the superior, bridges the angular interval between the ischiopubic rami (Figs. 6-37; 6-39). It is attached laterally to the medial borders of the rami from the arcuate pubic ligament to the ischial tuberosities. Along these same borders, the superior layer of the diaphragm is attached more deeply and the crura of the penis more superficially (Fig. 6-39). The middle portion of the fascia is pierced by the urethra and vagina and blends with their walls. It is perforated also by the arteries to the bulb, the ducts of the bulbourethral glands, the deep arteries of the penis, and the dorsal arteries and nerves of the penis. The part posterior to the urethra blends with the fascia of the bulb and, because of its attachment to the rami laterally, is sometimes called the **ligament of the bulb**. At these lateral attachments, the fascia also blends with that covering the crura of the penis. The part anterior to the urethra arches across the subpubic angle and is sometimes called the **transverse ligament of the pelvis**. The latter is separated from the symphysis pubis and arcuate pubic ligament by an opening for the passage of the dorsal vein of the penis. At the posterior border of the deep transversus muscle, the superficial and deep layers of the urogenital diaphragm fuse into a single layer and blend with the inferior fascia of the pelvic diaphragm from within the ischiorectal fossa.

The **external perineal fascia** (Figs. 6-36 to 6-39) is a fascial sheet, the existence of which is controversial, although it is described by some anatomists. Its defenders claim it to be an external investing layer of deep fascia in the urogenital region (in contrast to the inferior fascia of the urogenital diaphragm, which is thought by them to be the internal investing layer). It is considered to be the most superficial layer of the deep fascia in the urogenital region of the perineum, and to cover approximately the same triangular area as the inferior fascia of the urogenital diaphragm. Not being flat, the fascia is described as accommodating itself to the contours of the superficial perineal mus-

cles. Those denying the existence of this fascial plane consider the aforementioned connective tissue to be simply the epimysium of the superficial perineal muscles.

A detailed account of the external perineal fascia will be omitted from this edition because it is not a generally accepted structure and because it is not recognized in the *Nomina Anatomica*. The importance of considering it at all relates to the fact that those authors claiming it to be a fascial sheet have further described it, rather than Colles' fascia, as the superficial limiting boundary of the superficial perineal compartment. Additionally, its proponents claim the existence of a superficial perineal fascial cleft between the external perineal fascia and Colles' fascia.

**PERINEAL BODY.** The perineal body, often called the central tendinous point of the perineum, is a mass of fibromuscular tissue in the midline between the anus and the bulb of the penis in the male and between the anus and vagina in the female. It is approximately 2 cm in width and depth in the male and about twice this dimension in the female. It is composed predominately of fibrous tissue since it represents a fusion of the superior and inferior fasciae of the urogenital diaphragm and Colles' fascia (and perhaps the external perineal fascia). It contains a few muscular fibers also, principally from the pubococcygeal portions of the two levator ani muscles and the external anal sphincter. Besides these muscles, the perineal body also has attached to it the transversus perinei profundus and superficialis muscles of both sides as well as the bulbospongiosus muscle. It is directly continuous anteriorly with the fibrous tissue that fills in the genital hiatus between the two pubococcygei. It continues deep into the pelvis with the rectoprostatic and rectovesical septum in the male and the rectovaginal septum in the female. The perineum is a time-honored surgical approach to the bladder and prostate, and it is the site of the perineal tears that frequently result from childbirth.

**DEEP PERINEAL COMPARTMENT** (space or pouch). The deep perineal compartment is that region between the superior and inferior fascial layers of the urogenital diaphragm. The compartment is principally occupied by the transversus perinei profundus, but contains also the sphincter urethrae and the membranous portion of the urethra,

the bulbourethral glands (vestibular glands in the female) and their ducts, the internal pudendal vessels, the deep dorsal vein of the penis, and the dorsal nerve of the penis. The internal pudendal artery enters the deep perineal compartment posteriorly and its branches to the penile bulb, to the urethra, and to the deep and the dorsal arteries of the penis pierce the inferior fascia of the urogenital diaphragm to reach their destination.

**SUPERFICIAL PERINEAL COMPARTMENT** (space or pouch). The superficial perineal compartment is bounded by the inferior layer of the urogenital diaphragm and the deep layer of superficial fascia (Colles' fascia). (The proponents of the existence of the external perineal fascia state that it forms the superficial boundary of the pouch, instead of Colles' fascia.) The superficial perineal pouch contains the bulbospongiosus, ischiocavernosus, and transversus perinei superficialis muscles, and it is traversed by the perineal vessels and nerve.

**CLINICAL CONSIDERATIONS.** Extreme trauma may result in rupture of the urethra or even the bladder. Depending on the site of rupture (i.e., whether it occurs above or below the urogenital diaphragm), urine accumulates in either the pelvis or the perineum. Thus, because it is located above the urogenital diaphragm, if the bladder or prostatic urethra is ruptured, as is frequently the case with a fracture of the pelvis, extravasated urine collects in the extraperitoneal tissues of the pelvis and is prevented from spreading into the perineum by the pelvic diaphragm.

Rupture of the spongy or bulbous part of the urethra, which is below the urogenital diaphragm, is a common result of straddle injuries that occur when the pubic arch forcibly strikes an unyielding object such as a fencetop or a saddle. In these instances, urine is extravasated into the perineum, since the urogenital diaphragm limits its movement into the pelvis. If the deep fascia of the penis (Buck's fascia<sup>1</sup>) remains intact, urine is confined by this fascial plane to the penis only. More often, however, the deep fascia of the penis is also punctured, and urine escapes into the superficial perineal compartment. When this occurs, the urine is limited in its extravasation by the attachments of Colles' fascia and the fasciae with which it is continuous, the dartos layer over the scrotum, the superficial fascia of the penis, and the deep layer of superficial fascia over the anterior abdominal wall (Scarpa's fascia). Urine is usually prevented from spreading posteriorly into the anal region of the perineum or laterally into the thigh

<sup>1</sup>Gurdon Buck (1807-1877): An American surgeon (New York).

by the attachments of the inferior fascia of the urogenital diaphragm, Colles' and Scarpa's fasciae. Instead, urine extravasates into the scrotum, penis, and anterior abdominal wall, and in poorly attended cases, it may reach as high as the anterior thoracic wall.

### Perineal Muscles

The muscles of the perineum may be divided into two groups:

- Muscles of the urogenital region
  - In the male
  - In the female
- Muscles of the anal region

### MUSCLES OF THE UROGENITAL REGION IN THE MALE

#### Superficial Group

- Transversus perinei superficialis
- Bulbospongiosus
- Ischiocavernosus

#### Deep Group

- Transversus perinei profundus
- Sphincter urethrae

**TRANSVERSUS PERINEI SUPERFICIALIS.** This muscle is a narrow slip on each side that passes more or less transversely across the perineal area in front of the anus (Figs. 6-38; 6-40). It arises by tendinous fibers from the inner and anterior part of the tuberosity of the ischium, and, coursing medially, is inserted centrally into the perineal body, joining at this site with the muscle of the opposite side, the external anal sphincter posteriorly, and the bulbospongiosus anteriorly. In some instances, the fibers of the deeper layer of the external anal sphincter decussate in front of the anus and are continued into this muscle. Occasionally, the superficial transverse perineal muscle gives off fibers that join with the bulbospongiosus of the same side.

**Actions.** The simultaneous contraction of the two muscles serves to fix the centrally located perineal body.

**Variations.** The transversus perinei superficialis may be absent or doubled, or it may insert into the bulbospongiosus or external anal sphincter.

**THE BULBOSPONGIOSUS.** This muscle (formerly called accelerator urinae or bulbocavernosus) is placed in the midline of the perineum, ventral to the anus (Fig. 6-40). It

consists of two symmetrical parts, united along the median line by a tendinous raphe. It arises from the perineal body and its ventral extension into the median raphe. Its fibers diverge like the barbs of a feather. The most posterior fibers form a thin layer, which is lost on the inferior fascia of the urogenital diaphragm. The middle fibers encircle the bulk and adjacent parts of the corpus spongiosum penis, and join with the fibers of the opposite side, on the upper part of the corpus cavernosum penis, in a strong aponeurosis. The anterior fibers spread out over the side of the corpus cavernosum penis and are inserted partly into that body, anterior to the ischiocavernosus, occasionally extending to the pubis, and partly end in a tendinous expansion that covers the dorsal vessels of the penis. The latter fibers can be seen by dividing the muscle longitudinally and reflecting it from the surface of the corpus spongiosum penis.

**Actions.** The bulbospongiosus serves to empty the urethra, after the bladder has expelled its contents. During the greater part of the act of micturition its fibers are relaxed, and it only comes into action at the end of the process. The middle fibers assist in the erection of the corpus spongiosum penis by compressing the erectile tissue of the bulb. The anterior fibers also contribute to the erection of the penis by compressing the deep dorsal vein of the penis as these fibers insert into the penile fascia, which encases the dorsal vessels of the penis.

**THE ISCHIOCAVERNOSUS.** This muscle (at one time called the erector penis) is paired, each covering one of the crura of the penis (Fig. 6-40). It is an elongated muscle, broader in the middle than at either end, and situated at the lateral boundary of the perineum. It arises by tendinous and fleshy fibers from the inner surface of the tuberosity of the ischium dorsal to the crus penis, and from the rami of the pubis and ischium on each side of the crus. From these points, fleshy fibers course ventrally along the crus and end in an aponeurosis, which is inserted into the sides and undersurface of the crura as they become the body of the penis.

**Action.** The ischiocavernosus compresses the crus penis, retarding the return of the blood through the veins, and thus serves to maintain penile erection.

**TRANSVERSUS PERINEI PROFUNDUS.** This muscle arises from the inferior rami of the

**Fig. 6-40.** Muscles of the male perineum. The inferior fascia of the urogenital diaphragm has been removed on the right to reveal the transversus perinei profundus muscle and the bulbourethral gland. (After Sobotta.)

ischium and runs to the median line, where it interlaces in a tendinous raphe with its fellow of the opposite side (Figs. 6-37; 6-39; 6-40). Lying in the same plane as the sphincter urethrae, these two muscles are interposed between the superior and inferior fascial layers of the urogenital diaphragm and form much of the bulk of that structure. Formerly these two muscles were described together as the constrictor urethrae.

**SPHINCTER URETHRAE.** In the male, this muscle surrounds the whole length of the membranous portion of the urethra and is enclosed in the fasciae of the urogenital diaphragm. Its external fibers arise laterally along about 2 cm of the ischiopubic ramus and from the neighboring fasciae. They arch across the front of the urethra and bulbourethral glands. Passing around the urethra, the superficial fibers unite posterior to the urethra with muscle fibers from the opposite side by means of a tendinous raphe. Its internal fibers form a continuous circular investment for the membranous urethra.

**Actions.** The **sphincter urethrae** muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During micturition, like the bulbospongiosus, the sphincter urethrae muscles are relaxed, and only come into action at the end of the process to eject the last drops of urine. They also function during ejaculation.

**Nerve Supply.** All the muscles of the male urogenital region are supplied by the second, third, and fourth sacral nerves by way of the **perineal branch of the pudendal nerve**.

#### MUSCLES OF THE UROGENITAL REGION IN THE FEMALE

Transversus perinei superficialis  
Bulbospongiosus  
Ischiocavernosus  
Transversus perinei profundus  
Sphincter urethrae

**TRANSVERSUS PERINEI SUPERFICIALIS.** In the female this muscle is a narrow slip of fibers that arises by a small tendon from the

inner and ventral part of the tuberosity of the ischium and is inserted into the perineal body (Fig. 6-41). At this centrally located site of the perineum, as in the male, it joins the muscle of the opposite side, the external anal sphincter, and the bulbospongiosus.

**Action.** The simultaneous contraction of the two **transverse perinei superficialis** muscles serves to fix the perineal body.

**THE BULBOSPONGIOSUS.** This muscle has also been called the sphincter vaginae, and it surrounds the orifice of the vagina. It covers the lateral parts of the vestibular bulb and is attached posteriorly to the perineal body, where it blends with the external anal sphincter (Fig. 6-41). Its fibers pass anteriorly on each side of the vagina to be inserted into the corpora cavernosa clitoridis. A small muscular fasciculus also crosses over the body of the clitoris and compresses its deep dorsal vein.

**Actions.** The **bulbospongiosus** diminishes the orifice of the vagina. The anterior fibers contribute to the erection of the clitoris, being inserted into and continuous with the fascia of the clitoris and thereby compressing the deep dorsal vein during the contraction of this muscle.

**THE ISCHIOCAVERNOSUS.** In the female, this muscle (formerly called the erector clitoridis) is smaller than the corresponding muscle in the male. It covers the unattached surface of the crus clitoridis and is elongated, broader at the middle than at either end, and situated along the lateral boundary of the perineum (Fig. 6-41). It arises by tendinous and fleshy fibers from the inner surface of the tuberosity of the ischium, from the surface of the crus clitoridis, and from the adjacent portion of the ramus of the ischium. From these points fleshy fibers extend anteriorly and end in an aponeurosis, which is inserted into the sides and undersurface of the crus clitoridis.

**Actions.** The **ischiocavernosus** compresses the crus clitoridis, retarding the return of blood through the veins, and thus serves to maintain erection of the clitoris.

**UROGENITAL DIAPHRAGM IN THE FEMALE.** The urogenital diaphragm in the female, as in the male, is formed of two layers of fascia between which are interposed the deep transverse perineal muscle and the urethral sphincter. The fascial layers are not so strong in the female as in the male. Being attached to the pubic arch, the apices of the

**FIG. 6-41.** Muscles of the female perineum. The fat pad of the ischioanal fossa has been removed to reveal the levator ani muscle.

fascial layers are connected to the arcuate pubic ligament. Divided in the midline by the aperture of the vagina, the fasciae blend with the external coat of the vagina. Anterior to this the urogenital diaphragm is perforated by the urethra. The posterior borders of the fasciae, as in the male, are continuous with the deep layer of the superficial fascia around the transversus perinei superficialis.

Between the two fascial layers are found the deep dorsal vein of the clitoris, a portion of the urethra, the deep transverse perineal muscle and the sphincter urethrae muscle, the greater vestibular glands and their ducts, the internal pudendal vessels, the dorsal nerves of the clitoris, the arteries and nerves of the vestibular bulb, and a plexus of veins.

**TRANSVERSUS PERINEI PROFUNDUS.** In the female, the deep transverse perineal muscle courses from the inferior ramus of the ischium to the side of the vagina, meeting fibers of the muscle from the opposite side.

**Action.** The transversus perinei profundus helps to fix the perineal body.

**SPHINCTER URETHRAE.** Like the corresponding muscle in the male, the sphincter urethrae in the female consists of external and internal fibers. The external fibers arise on each side from the margin of the inferior ramus of the pubis and the transverse perineal ligament. They are directed across the pubic arch in front of the urethra, and pass around it to blend with the muscular fibers of the opposite side, between the urethra and vagina. The internal fibers encircle the lower end of the urethra.

**Action.** The sphincter urethrae of the two sides act together as a constrictor of the urethra.

**Nerve Supply.** All the muscles of the female urogenital region are supplied by the second, third, and fourth sacral nerves by way of the perineal branch of the pudendal nerve.

#### MUSCLES OF THE ANAL REGION

Corrugator cutis ani  
Sphincter ani externus  
Sphincter ani internus

**CORRUGATOR CUTIS ANI.** Around the anus is a thin stratum of involuntary muscle and yellow elastic fibers that radiates from the orifice. Medially the fibers fade into the submucous tissue, while laterally they blend with the true skin.

**Action.** By its contraction the corrugator cutis ani muscle puckers the skin, raising it into ridges around the anal orifice.

**EXTERNAL ANAL SPHINCTER.** The external anal sphincter is a flat plane of muscular fibers, elliptical in shape and intimately adherent to the integument surrounding the margin of the anus. It measures about 8 to 10 cm from its anterior to its posterior extremity, and is about 2.5 cm broad opposite the anus. It surrounds the last 2 cm of the anal canal and consists of three parts, subcutaneous, superficial, and deep. The **subcutaneous lamina** is a band of fibers that lies beneath the skin surrounding the anal orifice. Some fibers are attached anteriorly to the perineal body and posteriorly to the anococcygeal ligament. The **superficial lamina** lies deep to the subcutaneous lamina and constitutes the main portion of the muscle. It also arises from the narrow tendinous anococcygeal ligament, which stretches from the tip of the coccyx to the posterior margin of the anus. The muscle fibers then encircle the anus and meet in front to be inserted into the perineal body, joining with fibers from the transversus perinei superficialis, the levator ani, and the bulbospongiosus. The **deep layer** forms a complete sphincter to the anal canal. Its fibers surround the canal, closely applied to the internal anal sphincter, and its deep fibers are interlaced with fibers of the puborectalis muscle. In front, the deep part of the external anal sphincter blends with the other muscles at the perineal body. In many individuals, the fibers decussate in front of the anus and are continuous with those of both transversus perinei superficialis muscles. Posteriorly, they are not attached to the coccyx, but are continuous with those of the opposite side behind the anal canal. The upper edge of the muscle is ill defined because some fibers join with those of the levator ani muscle.

**Actions.** The action of the external anal sphincter is peculiar. Like some muscles, this muscle is always in a state of tonic contraction, and having no antagonistic muscle, it serves to keep the anal canal and orifice closed. Under voluntary control, the muscle can be made to contract more firmly, thereby occluding the anal aperture in expiratory efforts unconnected with defecation. Considering its bony attachment by way of the anococcygeal ligament at the coccyx, it helps to fix the perineal body so that the bulbospongiosus may act from this fixed point. During defecation the muscle relaxes, thereby

allowing the contents of the anal canal and rectum to be eliminated.

**Nerve Supply.** The external anal sphincter is supplied by a branch from the fourth sacral and twigs from the inferior rectal branch of the **pudendal nerve**.

**INTERNAL ANAL SPHINCTER.** The internal sphincter of the anus is a muscular ring that surrounds about 2.5 cm of the anal canal. Its inferior border is in contact with, but quite separate from, the external sphincter. It is about 5 mm thick, and is formed by an aggregation of the involuntary circular fibers of the intestine. Its distal border is about 6 mm from the orifice of the anus.

**Actions.** The action of the **internal anal sphincter** is entirely involuntary. It helps the external sphincter to occlude the anal aperture and aids in the expulsion of the feces.

**Nerve Supply.** The internal anal sphincter is supplied by fibers of the **autonomic nervous system** as is the musculature surrounding many of the abdominal and pelvic organs.

## Muscles and Fasciae of the Upper Limb

The structures of the upper limb will be described under the following headings:

- Muscles connecting the upper limb to the vertebral column
- Muscles connecting the upper limb to the thoracic wall
- Muscles of the shoulder
- Muscles of the arm
- Muscles of the forearm
- Fasciae, retinacula, synovial sheaths, and compartments of the wrist and hand
- Muscles of the hand

### MUSCLES CONNECTING THE UPPER LIMB TO THE VERTEBRAL COLUMN

- Trapezius
- Latissimus dorsi
- Rhomboid major
- Rhomboid minor
- Levator scapulae

**SUPERFICIAL FASCIA.** The superficial fascia of the back is a thick fibrous and fatty layer that extends from the scalp to the gluteal

region as a comparatively uniform sheet. At the sides of the neck and trunk, it gradually changes into a thinner or softer fascia characteristic of the more anterior regions. The dermal fibrous layer is thick and is bound down to the deeper layers by numerous heavy bands and septa, which divide the fat into small granular lobules and mattress the entire layer into a tough, resilient pad. The fascial cleft, usually present between the superficial and deep fascia, is lacking in the dorsal regions, making the superficial fascia firmer and less movable than that in the anterior parts of the trunk and neck.

**DEEP FASCIA.** The **investing layer of deep fascia** is attached in the midline to the ligamentum nuchae, the supraspinal ligament, and the spinous processes of all vertebrae caudal to the sixth cervical. It splits to enclose the trapezius and the fleshy portion of the latissimus dorsi, but in the neck it covers the posterior triangle as a single layer and there becomes continuous with the investing layer of fascia of the anterior neck. It is attached, over the shoulder, to the acromion and spine of the scapula, and is then continuous with the deltoid fascia. Laterally from the latissimus, it is continuous with the axillary fascia above and with the deep fascia covering the external oblique muscle of the abdominal wall. Over the fleshy portions of the trapezius and latissimus, it is gray and felt-like, but strong and adherent both to the superficial fascia and to the muscles. In a triangular area bounded by the trapezius, deltoid, and latissimus, it is white and glistening, forming an aponeurotic fascia over the infraspinatus. In the lumbar region, the deep fascia is greatly strengthened by having incorporated in it the aponeurosis of origin of the latissimus dorsi. This portion constitutes the posterior layer of the thoracolumbar fascia.

The investing fascia lining the deep surface of the trapezius is thickened by an accumulation of adipose tissue similar to that under the pectoralis major. Within its course the transverse cervical artery, its superficial (ascending) branch, and the accessory nerve. The fascia lining the deep surface of the fleshy portion of the latissimus is similar to that of the trapezius, but over the aponeurosis of the latissimus it loses its identity as a separate layer and is fused with the thoracolumbar fascia.

The rhomboid muscles and the levator

scapulae are enclosed in their own proper fascial sheaths, which are attached to the vertebrae and to the vertebral border of the scapula. The fascia along the superficial surface of these muscles, after attaching to the border of the scapula, continues laterally as the supra- and infraspinatus fasciae. The fascia deep to these muscles continues laterally on the deep surface of the serratus anterior, and a distinct fascial cleft separates both superficial and deep surfaces of the rhomboids from contiguous structures. The fascia surrounding the levator scapulae is more adherent to surrounding structures and is continuous with the scalene fascia over the anterolateral aspect of the neck.

**THE TRAPEZIUS.** The trapezius is the flat and triangular muscle that covers the posterior part of the neck, shoulders, and thorax (Fig. 6-42). It arises from the external occipital protuberance and the medial third of the superior nuchal line of the occipital bone, from the ligamentum nuchae, the spinous process of the seventh cervical, and the spinous processes of all the thoracic vertebrae, and from the corresponding supraspinal ligaments. From this origin, the superior fibers proceed downward and laterally, the inferior upward and laterally, and the middle horizontally. The superior fibers are inserted into the posterior border of the lateral third of the clavicle; the middle fibers into the medial margin of the acromion and into the superior lip of the posterior border of the spine of the scapula; the inferior fibers converge near the scapula and end in an aponeurosis that glides over the smooth triangular surface on the medial end of the scapular spine and are inserted into a tubercle at the apex of this surface. At its occipital origin, the trapezius is connected to the bone by a thin fibrous lamina, firmly adherent to the skin. The middle part is connected to the spinous processes by a long triangular aponeurosis that reaches from the sixth cervical to the third thoracic vertebra, and joins with that of the opposite muscle to form a diamond-shaped tendinous area, observable as a hollow area in the middle of the back of the living subject. The rest of the muscle arises by numerous short tendinous fibers. The two trapezius muscles together resemble a trapezium, or diamond-shaped quadrangle: the two lateral angles correspond to the shoulders; the third to the occipital protuberance superiorly; and the fourth to the

spinous process of the twelfth thoracic vertebra inferiorly.

**Action.** The **trapezius muscle**, especially the upper and lower fibers, functions most importantly in *rotation of the scapula*, so that the glenoid fossa is made to face upward as is necessary in full abduction of the upper extremity. This movement is performed by the upper fibers pulling superiorly on the acromion and lateral aspect of the scapular spine and the lower fibers pulling inferiorly on the medial aspect of the scapular spine. Rotation is assisted by the serratus anterior muscle.

The upper part acting alone *elevates the shoulder*, thereby bracing the shoulder girdle when a weight is being carried either on the shoulder or by the hand (Mortensen and Wiedenbauer, 1952; Bearn, 1961). The lower part *draws the scapula downward*. With both muscles acting together, the scapulae can be adducted and the head drawn directly backward.

**Nerve.** The trapezius muscle receives its motor nerve supply from the spinal part of the **spinal accessory nerve**. It also receives sensory branches (proprioceptive) from the ventral primary divisions of the **third and fourth cervical nerves**.

**Variations.** Variations in the structure of the trapezius muscle can occur. Its attachments to the thoracic vertebrae are often reduced and the inferior ones absent. The occipital attachment may be small or wanting, and the clavicular attachment may be reduced, but is more often enlarged, covering most of the posterior triangle. The cervical and thoracic portions may be separate. The muscles of the two sides are seldom symmetrical, and aberrant bundles are not uncommon. Complete absence of the trapezius has been described.

**LATISSIMUS DORSI.** The latissimus dorsi is a large triangular muscle that covers the lumbar and lower half of the posterior thoracic region (Fig. 6-42). Its origin is principally in a broad aponeurosis, which joins the posterior layer of the thoracolumbar fascia (Fig. 6-18). By this means it is attached to the spinous processes of the lower six thoracic, the lumbar, and the sacral vertebrae; to the supraspinal ligament; and to the posterior part of the crest of the ilium. It also arises by muscular fasciculi from the external lip of the crest of the ilium lateral to the margin of the erector spinae, and from the caudal three or four ribs by fleshy digitations that are interposed between similar processes of the external abdominal oblique muscle (Fig. 6-26). From this extensive origin, the fasciculi converge toward the upper humerus. Those of the upper part are almost horizontal and, as they pass over the inferior angle of the scapula, are joined by additional fasciculi

FIG. 6-42. Muscles connecting the upper limb to the vertebral column.

arising from this bone. The muscle curves around the lower border of the *teres major*, twisting upon itself so that the superior fibers become initially posterior and then inferior, and the vertical fibers at first are anterior and then are superior. The muscle ends in a quadrilateral tendon about 7 cm long, which passes anterior to the tendon of the *teres major* and is inserted into the bottom of the intertubercular groove of the humerus. Its insertion extends farther proximally on the humerus than that of the tendon of the *pectoralis major*. The inferior border of the latissimus tendon is united with that of the *teres major*, their tendons being separated near their insertions by a bursa underlying the tendon of the latissimus dorsi (Fig. 6-47). Another bursa is sometimes interposed between the muscle and the inferior angle of the scapula. At its insertion, the latissimus tendon gives off an expansion to the deep fascia of the arm.

**Action.** The latissimus dorsi extends, adducts, and rotates the humerus medially. It is a powerful swimming muscle, allowing the upper limbs to downstroke against the resistance of the water. With its insertion into the upper extremity fixed, this muscle is one of the most important climbing muscles because it elevates the trunk toward the arms when they are stretched above the head.

The latissimus also aids in the forced expiratory movements of sneezing and coughing, as well as in deep inspiration. Additionally, through its attachment onto the humerus, it can rotate the scapula downward, such movement being required when the shoulders must bear the weight of the body in the use of crutches.

**Nerve.** The latissimus dorsi is supplied by the thoracodorsal nerve (C6,7,8) from the posterior cord of the brachial plexus.

**Variations.** The number of thoracic vertebrae to which the latissimus dorsi is attached varies from four to eight. The number of costal attachments varies, and the muscle fibers may or may not reach the crest of the ilium.

A muscular slip, the axillary arch, varying from 7 to 10 cm in length and from 5 to 15 mm in breadth, occasionally springs from the upper border of the latissimus dorsi about the middle of the posterior fold of the axilla. When present, it crosses the axilla in front of the axillary vessels and nerves, and joins the deep surface of the tendon of the *pectoralis major*, the *coracobrachialis*, or the fascia over the biceps. Because the axillary arch crosses the axillary artery just above the site usually selected for application of a ligature, it may mislead the surgeon during that procedure. It is present in about 7% of subjects and may be easily recognized by the transverse direction of its fibers.

A fibrous slip usually passes from the inferior border of the tendon of the latissimus dorsi, near its insertion, to the long head of the *triceps brachii*. This slip is occasionally muscular and is the representative of the *dorsoepitrochlearis brachii* of apes.

**Clinical Considerations.** The lumbar triangle (of Petit<sup>1</sup>) is a small triangular interval that separates the lateral margin of the lower portion of the latissimus dorsi from the external abdominal oblique muscle just above the ilium. The base of the triangle is the iliac crest, and its floor is formed by the internal abdominal oblique muscle. It is occasionally the site of an abdominal hernia.

The triangle of auscultation is a landmark of clinical importance associated with the upper portion of the latissimus. This triangle is bounded superiorly by the trapezius, inferiorly by the latissimus dorsi, and laterally by the vertebral border of the scapula. The floor is partly formed by the rhomboid major. If the scapula is drawn anteriorly by folding the arms across the chest, and the trunk bent forward, parts of the sixth and seventh ribs and their interspace become subcutaneous and accessible for auscultation.

**RHOMBOID MAJOR.** The rhomboid major (Fig. 6-42) arises by tendinous fibers from the spinous processes of the second, third, fourth, and fifth thoracic vertebrae and the supraspinal ligament. Its fibers course inferolaterally to be inserted by a narrow tendinous arch to the medial border of the scapula between the triangular surface at the root of the scapular spine above and the inferior angle of the scapula below. Usually the muscle fibers terminate in a tendinous arch, which then is attached to the scapula by a thin membrane. Occasionally, however, the muscle fibers are inserted directly into the scapula.

**RHOMBOID MINOR.** The rhomboid minor (Fig. 6-42) arises from the inferior part of the ligamentum nuchae and from the spinous processes of the seventh cervical and first thoracic vertebrae. Its fibers course inferolaterally just superior to the rhomboid major to be inserted into the base of the triangular smooth surface at the root of the spine of the scapula. The rhomboid minor is usually separated from the rhomboid major by a slight interval, but the adjacent margins of the two muscles are occasionally united.

**Action.** The rhomboid major and minor muscles adduct the scapula by pulling it medially toward the vertebral column. They also support the scapula by elevating it, especially when weights are placed

<sup>1</sup>Jean Louis Petit (1674-1750); French anatomist and surgeon (Paris).

on the shoulder or carried by the upper extremity. The lower part of the rhomboid major rotates the scapula to depress the lateral angle, assisting in adduction of the upper extremity.

**Nerve.** The rhomboid muscles are supplied by the **dorsal scapular nerve** from the brachial plexus, containing fibers from the fifth cervical nerve.

**Variations.** The vertebral and scapular attachments of the two rhomboid muscles vary in extent. A small slip, which is called the **rhomboid occipitalis**, is occasionally found extending from the scapula to the occipital bone.

**LEVATOR SCAPULAE.** This narrow elongated muscle is situated at the dorsal and lateral part of the neck (Fig. 6-42). It arises by tendinous slips from the transverse processes of the atlas and axis and from the posterior tubercles of the transverse processes of the third and fourth cervical vertebrae. It descends deep to the sternocleidomastoid, along the floor of the posterior triangle of the neck, and then under cover of the trapezius to be inserted into the vertebral border of the scapula, between the superior angle and the triangular smooth surface at the root of the spine.

**Action.** The **levator scapulae** elevates the superior angle of the scapula, tends to draw the scapula medially, and rotates it so as to lower the lateral angle. With the scapula fixed, the **levator scapulae** bends the neck laterally and rotates it slightly toward the same side.

**Nerves.** The **levator scapulae** is supplied directly by branches of the **third and fourth cervical nerves** from the cervical plexus. Frequently the lower portion of the muscle receives a branch of the **dorsal scapular nerve**, containing fibers from the fifth cervical nerve.

**Variations.** The number of vertebral attachments of the **levator scapulae** varies. A slip may extend to the occipital or mastoid bones; to the trapezius, scalene, or serratus anterior; or to the first or second rib. The muscle may be subdivided into several distinct parts from origin to insertion. A slip from the transverse processes of one or two upper cervical vertebrae to the outer end of the clavicle corresponds to the **levator claviculae** muscle of lower animals. More or less union with the serratus anterior is not uncommon.

#### MUSCLES CONNECTING THE UPPER LIMB TO THE THORACIC WALL

Pectoralis major  
Pectoralis minor

Subclavius  
Serratus anterior

**SUPERFICIAL FASCIA.** The superficial fascia of the pectoral region is continuous with that of the neck superiorly, the abdomen inferiorly, and the axilla and upper extremity laterally. The fasciculi of the platysma muscle extend down from the neck for a variable distance between its superficial and deep layers. In the female, the adipose tissue is increased and molded into a rounded mass, which gives the bulk and form to the mammary gland. The parenchyma of the gland is embedded in this fat, and thus the entire gland is located within the superficial fascia. The connective tissue stroma, distributed between the lobes of the gland, is thickened into fibrous bands called the **suspensory ligaments** (of Cooper), which secure the skin to the deep layer of superficial fascia. A fascial cleft separates the superficial fascia from the deep fascia, allowing the mammary gland in its entirety to be easily removed from the underlying pectoralis major muscle. Through these fascial structures, carcinoma of the breast may make its presence known either by pulling on Cooper's ligaments and dimpling the skin like an orange peel, or by interfering with the normal movability of the gland due to adhesions between the superficial and deep fasciae.

**PECTORAL FASCIA.** The pectoral fascia (Fig. 6-43) is a membranous sheet of deep fascia that consists of external investing fascia superficial to the pectoralis major and a deeper layer enclosing its inner surface. Its bony attachments are consistent throughout with those of the pectoralis major muscle, i.e., to the clavicle and sternum and to the humerus. The external layer is continuous medially, across the midline, with the pectoral fascia of the other side; superiorly and laterally, with the brachial fascia that covers the coracobrachialis and biceps muscles; and inferiorly, with the axillary, thoracic, and abdominal investing fasciae. At the more inferior sternocostal and abdominal origins of the pectoralis major muscle, the fascia is aponeurotic and is blended with the sheath of the rectus abdominis. The layer covering the deep surface of the muscle is thickened by a considerable pad of fat in which the thoracoacromial blood vessels and pectoral nerves are embedded. A definite fascial cleft separates this layer from the underlying

Fig. 6-43. Fasciae of axillary and pectoral regions in sagittal section.

**clavipectoral fascia** (Fig. 6-43). The external and the deeper layers fuse at the borders of the muscle, forming a closed compartment. Beyond the superior border, the fascia separates again to enclose the deltoid muscle. Beyond the inferolateral border, however, a single sheet is formed which immediately becomes the **axillary fascia**.

**CLAVIPECTORAL FASCIA.** The clavipectoral fascia is a stratum of deep fascia that lies between the deep layer of pectoral fascia and the thoracic wall (Fig. 6-43). It invests the pectoralis minor and subclavius muscles and extends from the clavicle to the axillary fascia. It attaches to the clavicle by means of two membranes which lie superficial and deep to the subclavius and are separated from each other by the insertion of the muscle. The two sheets form a compartment for the subclavius by fusing at the muscle's inferior border into a single sheet, which stretches across the interval between the subclavius and the pectoralis minor. Extending laterally to the coracoid process and medially to the first rib, this fascia becomes strengthened by the addition of fibrous bundles to form the **costocoracoid ligament**.

This strong band helps to stabilize and brace the clavicle, thereby serving to strengthen the clavicular articulations both medially and laterally. From its attachment to the coracoid process, the fascia passes downward as a thin sheet, investing the pectoralis minor on both its surfaces and attaching to the ribs with the origin of this muscle. Between the ribs the clavipectoral fascia is continuous with the external intercostal fascia. At the superior border of the pectoralis minor, the two layers investing the muscle fuse into the single sheet that bridges the triangular interval between the pectoralis minor and the subclavius. This single sheet is thin below the ligament and has one or more openings through which pass the thoracoacromial artery and vein, the cephalic vein, and the lateral pectoral nerve. At the inferior or lateral border of the pectoralis minor, the two layers that enclose the muscle combine again into a single sheet, which then passes into the axilla and fuses with the deep surface of the axillary fascia a short distance from the lateral border of the pectoralis major. The axillary sheath, which encloses the axillary vessels and the nerves of

the brachial plexus, passes deep to the clavipectoral fascia and is separated from it by some of the fat in the deep axilla.

**AXILLARY FASCIA.** The portion of investing fascia called the axillary fascia (Fig. 6-43) crosses the interval between the lateral borders of the pectoralis major and latissimus dorsi and dips inward to form the hollow of the armpit. It is adherent to the superficial fascia and is continuous with the pectoral, latissimus, serratus, and brachial fasciae. Fused with its deep surface in the hollow of the armpit is the termination of the clavipectoral fascia, which has continued laterally from the pectoralis minor and is named the **suspensory ligament of the axilla**. It is believed that the hollow of the armpit, seen when the arm is abducted, is produced mainly by the traction of this suspensory ligament on the axillary floor.

**THE AXILLA.** The axilla comprises more than the externally visible armpit. It is a region, shaped like a pyramid, between the medial side of the arm and the lateral surface of the chest wall. Its base is directed inferolaterally and is formed by the skin of the armpit, while its apex is bounded by the approximation of three bones—the first rib, the clavicle, and the coracoid process. The axilla is filled with adipose tissue through which course the important vessels and nerves that supply the upper extremity. Additionally, many lymphatics draining the upper extremity and the anterior chest wall (including the mammary gland) are located in the axilla. The walls of the axilla are formed by the fascial coverings over the following muscles: *anteriorly*, the pectoralis major and minor; *posteriorly*, the latissimus dorsi, teres major, and subscapularis; *medially*, the serratus anterior; and *laterally*, the coracobrachialis and biceps (Fig. 6-45). At the apex of the axilla, the adipose padding is continuous with a mass of similar tissue in the posterior triangle of the neck, and the fascia covering the first two ribs and first intercostal space is continuous with the scalene fascia of the cervical region. The latter fascia descends from the neck, deep to the clavicle, with the large vessels and nerves of the axilla to form a tubular investment for these structures called the **axillary sheath**. This sheath, partially adherent to the clavipectoral fascia on the deep surface of the subclavius and pectoralis minor as it passes under them, traverses the lateral wall of the

axilla along the coracobrachialis to become fused with the anterior surface of the medial intermuscular septum of the arm.

**PECTORALIS MAJOR.** The pectoralis major is a thick, fan-shaped muscle situated on the anterior and superior aspect of the chest (Fig. 6-44). It arises from the anterior surface of the sternal half of the clavicle; from half the breadth of the anterior surface of the sternum, as far down as the attachment of the cartilage of the sixth or seventh rib; from the cartilages of all the true ribs, with the exception, frequently, of the first and/or seventh; and from the aponeurosis of the external abdominal oblique muscle. The muscle fibers, from this extensive origin, converge toward the anterior wall of the axilla. The fibers of the **clavicular part** pass obliquely downward and laterally and are usually separated from the rest by a slight interval. The fibers of the **sternocostal part** course horizontally from the mid-sternum and its attached ribs, or ascend from the lower sternum and its associated ribs and costal cartilages. The fibers composing the **abdominal part** ascend almost vertically toward the axilla. All three parts of the muscle end in a flat tendon, about 5 cm broad, which is inserted into the lower end of the lateral lip of the intertubercular sulcus of the humerus. This tendon terminates in three laminae, which are oriented longitudinally and insert parallel to each other on the bone, the posterior two blending together below in the form of a U. The anterior lamina is the thickest and receives the clavicular fibers of the muscle. These descend directly and insert in the same order as that by which they arise, that is, the most lateral of the clavicular fibers are inserted at the most superior part of the anterior lamina and the most medial clavicular fibers insert most inferiorly in the lamina. The fibers of the sternocostal part fold upon themselves to form the middle and posterior laminae of insertion, which are continuous with each other inferiorly. The upper sternal fibers from the manubrium form the middle lamina, whereas the sternocostal fibers arising below the sternal angle and the fibers of the abdominal part form the posterior lamina of insertion. Because the lowermost fibers of the pectoralis major insert highest on the posterior lamina and those arising progressively higher on the sternum insert progressively lower on the posterior lamina, the sternocostal and

FIG. 6-44. Superficial muscles of the chest and anterior arm.

abdominal parts of the muscle give the twisted structure of the muscle at the anterior axillary fold. The posterior lamina extends more superiorly on the humerus than either of the other two. From this posterior lamina an expansion is given off which covers the intertubercular groove and blends with the capsule of the shoulder joint. From the deepest fibers of the posterior lamina at its insertion, a second expansion is given off which lines the intertubercular groove, while from the inferior border of the tendon a third expansion passes distally to the fascia of the arm.

**Action.** The primary action of the **pectoralis major** is adduction of the arm; however, it is also a medial rotator of the humerus, especially if resistance must be overcome (Scheving and Pauly, 1959).

The clavicular portion (along with the coracobrachialis and anterior fibers of the deltoid) helps to flex the humerus and adduct it medially across the midline. In contrast, the sternocostal portion (with the latissimus dorsi and teres major) can extend, against resistance, the flexed humerus to the side of the trunk.

**Nerves.** The pectoralis major muscle is supplied by the **medial and lateral pectoral nerves** from the brachial plexus, containing fibers from the fifth, sixth, seventh, eighth cervical, and first thoracic nerves.

**Variations.** The more frequent variations in the structure of the pectoralis major are a greater or lesser extent of attachment to the ribs and sternum, varying size of the abdominal part or its absence, a greater or lesser extent of separation of the sternocostal and clavicular parts, fusion of clavicular part with deltoid, or decussation of the two muscles in front of the sternum. Deficiency or absence of the

sternocostal part is not uncommon, but absence of the clavicular part is less frequent; rarely, the whole muscle is wanting.

The **costocoracoid** is a muscular band occasionally found arising from the ribs or aponeurosis of the external oblique between the pectoralis major and latissimus dorsi and inserting onto the coracoid process.

The **chondroepitrochlearis** is a muscular slip occasionally found arising from the costal cartilages or from the aponeurosis of the external oblique below the pectoralis major or from the pectoralis major itself. The insertion is variable onto the inner side of the arm to the brachial fascia, intermuscular septum, or medial epicondyle.

The **sternalis** is a small superficial muscle at the sternal end of the pectoralis major at right angles to its fibers and parallel with the margin of the sternum. It is supplied by the pectoral nerves, and when it is present, it is probably a misplaced part of the pectoralis.

**PECTORALIS MINOR.** The pectoralis minor is a thin, triangular muscle, situated on the

upper part of the thorax, deep to the pectoralis major (Fig. 6-45). It arises from the superior margins and outer surfaces of the third, fourth, and fifth ribs, near their cartilages, and from the aponeuroses covering the intercostal muscles. The fibers pass upward and laterally and converge to form a flat tendon, which is inserted into the medial border and superior surface of the coracoid process of the scapula.

**Action.** The pectoralis minor draws the scapula forward and downward, a movement called protraction. It also rotates the scapula so as to lower the lateral angle during adduction of the arm. If the scapula is fixed by the levator scapulae, the pectoralis minor raises the third, fourth, and fifth ribs during forced inspiration.

**Nerve.** The pectoralis minor muscle is supplied by the **medial pectoral nerve** from the brachial plexus, containing fibers from the eighth cervical and first thoracic nerves.

**Variations.** The origin of the pectoralis minor

FIG. 6-45. Deep muscles of the chest and front of the arm, with the boundaries of the axilla.

may extend from the second through the fifth ribs. The tendon of insertion may extend over the coracoid process to the greater tubercle of the humerus. The muscle may be split into several parts, but its complete absence is rare.

The **pectoralis minimus** is a slip from the cartilage of the first rib to the coracoid process and is found rarely.

**THE SUBCLAVIUS.** This small cylindrical muscle is placed between the clavicle and the first rib (Fig. 6-45). It arises by a short, thick tendon from the first rib and its cartilage at their junction. The fleshy fibers proceed obliquely upward and laterally to be inserted into the groove on the inferior surface of the middle third of the clavicle between the costoclavicular and conoid ligaments.

**Action.** The **subclavius** depresses and pulls forward the lateral end of the clavicle, thereby helping to stabilize that bone during movements at the shoulder joint.

**Nerve.** The **subclavius** is supplied by a special nerve from the lateral trunk of the brachial plexus which contains fibers from the **fifth and sixth cervical nerves**.

**Variations.** Insertion of the **subclavius** may occur onto the coracoid process of the scapula instead of the clavicle or onto both bones.

At times a slip of muscle called the **sternoclavicularis** extends from the manubrium to the clavicle between the **pectoralis major** and **coracoclavicular fascia**.

**SERRATUS ANTERIOR.** The **serratus anterior** is a thin muscular sheet that is situated between the ribs and the scapula, spreading over the lateral part of the chest (Fig. 6-45). It arises by fleshy digitations from the outer surfaces and superior borders of the first eight or nine ribs, and from the aponeuroses covering the intervening intercostal muscles. Each digitation (except the first) arises from the corresponding rib. The first springs from the first and second ribs and from the fascia covering the first intercostal space. The lower four slips interdigitate at their origins with the upper five slips of the external abdominal oblique muscle. From this extensive attachment the fibers pass backward, closely applied to the chest wall, to be inserted onto the ventral surface of the medial (vertebral) border of the scapula. The first digitation is inserted into a triangular area on the anterior surface of the superior angle. The next two digitations spread out to form

a thin, triangular sheet, the base of which is directed posteriorly and is inserted into nearly the whole length of the anterior surface of the vertebral border. The lower five or six digitations converge like a fan, the apex of which is inserted by muscular and tendinous fibers into a triangular impression on the anterior surface of the inferior angle.

**Action.** The **serratus anterior** draws the medial border of the scapula anteriorly close to the thoracic wall, thereby preventing the bone from protruding backward (winging) in reaching and pushing movements. Its upper fibers help suspend the scapula, while the lower fibers assist in upward rotation of the scapula by laterally rotating the inferior angle. This latter action raises the point of the shoulder, thereby helping in abduction of the arm. During the first 90° of abduction of the humerus, the **serratus anterior** helps to brace the scapula, allowing the **deltoid** to abduct the arm. When the arm is abducted to 90°, further abduction to 180° (raising the arm straight overhead) can only be accomplished by lateral rotation of the inferior angle of the scapula (i.e., upward rotation of the glenoid fossa), performed by the **serratus anterior** below and by both the upper and lower fibers of the **trapezius**.

**Nerve.** The **serratus anterior** is supplied by the **long thoracic nerve** from the brachial plexus, containing fibers from the fifth, sixth, and seventh cervical nerves.

**Variations.** Varying attachments of the **serratus anterior** include attachment to the tenth rib, absence of attachment to the first rib or to one or more of the lower ribs, attachment with the **levator scapulae**, **external intercostals**, or **external abdominal oblique muscles**. The muscle may be divided into three parts, and the middle part may be defective or absent.

## MUSCLES OF THE SHOULDER

Deltoid  
Subscapularis  
Supraspinatus  
Infraspinatus  
Teres minor  
Teres major

These six muscles of the shoulder all extend from the scapula to the humerus and act on the shoulder joint. The **deltoid**, which also attaches to the clavicle, overlies the other five and itself is covered by its deep fascial layer, the **deltoid fascia**.

**DELTOID FASCIA.** This **deltoid** portion of the investing fascia covers the **deltoid** muscle and is attached superiorly to the clavicle,

acromion, and spine of the scapula. Inferiorly, it is continuous with the brachial fascia, and anteriorly, it bridges the narrow triangular region between the adjacent borders of the deltoid and the pectoralis major. In this interval, called the **deltopectoral triangle**, the fascia is thick but is pierced by the cephalic vein and deltoid branch of the thoracoacromial artery. The deltoid fascia is stronger posteriorly and is continuous with the infraspinatus fascia. Along both borders of the deltoid, the investing layer fuses with the fascia lining the deep surface of the muscle to form a closed compartment. The deep layer may contain adipose tissue and is separated by a distinct fascial cleft from the underlying humerus, subdeltoid bursa, shoulder joint, and associated tendons and ligament.

**THE DELTOID.** The deltoid is a large, thick, triangular muscle that covers the shoulder joint anteriorly, posteriorly, and laterally (Fig. 6-44). It arises from the anterior and superior surfaces of the lateral third of the clavicle, from the lateral margin and superior surface of the acromion, and from the lower lip of the posterior border of the spine of the scapula, as far dorsally as the triangular surface at its medial end. From this extensive origin the fibers converge toward their insertion, the middle passing vertically, the anterior obliquely backward and laterally, and the posterior obliquely forward and laterally. They unite in a thick tendon, which is inserted into the deltoid tuberosity on the lateral aspect of the body of the humerus, midway along the shaft. At its insertion the muscle gives off an expansion to the deep fascia of the arm. The deltoid is remarkably coarse in texture, and the arrangement of its fibers is somewhat peculiar. The central portion of the muscle, arising from the acromion, consists of oblique fibers that are multipennate in form. These spring from the sides of interspersed tendons, generally four in number, which are attached above to the acromion and pass distally parallel to one another in the substance of the muscle. The fibers are attached to these four tendons above, and then attached to three similarly interspersed tendons which ascend from the deltoid tuberosity below. The portions of the muscle arising from the clavicle and spine of the scapula are not arranged in this manner, but attach directly into the margins of the tendon of insertion.

**Action.** The principal function of the **deltoid muscle** is abduction of the arm, an action that is initiated with the supraspinatus. Abduction is effected primarily by the multipennate acromial portion of the muscle, with the anterior and posterior fibers bracing the limb to steady the abducted arm. The clavicular portion aids the pectoralis major in flexing the arm, and the spinous portion aids the latissimus dorsi in extending the arm.

**Nerve.** The deltoid is supplied by the **axillary nerve** from the brachial plexus, containing fibers from the fifth and sixth cervical nerves.

**Variations.** Large variations in the structure of the deltoid muscle are uncommon, but more or less splitting is common. Continuation into the trapezius, fusion with the pectoralis major, additional slips from the vertebral border of the scapula, infraspinous fascia, and axillary border of scapula are not uncommon variations. Its insertion varies in extent and rarely is prolonged to the origin of the brachioradialis.

**SUBSCAPULAR FASCIA.** The subscapular fascia is a thin membrane attached to the entire circumference of the subscapular fossa, affording attachment by its deep surface to some of the fibers of the subscapularis muscle.

**THE SUBSCAPULARIS.** The subscapularis (Fig. 6-45) is a large triangular muscle that fills the subscapular fossa of the scapula; it arises from the medial two-thirds of this fossa and from the lower two-thirds of the groove on the lateral axillary border of the bone. Some fibers arise from tendinous laminae that intersect the muscle and are attached to ridges on the bone; others arise from an aponeurosis that separates the muscle from the teres major and the long head of the triceps brachii. The fibers pass laterally and, gradually converging, end in a tendon that is inserted into the lesser tubercle of the humerus and the anterior part of the capsule of the shoulder joint. The tendon of the muscle is separated from the neck of the scapula by a large bursa, which usually communicates with the cavity of the shoulder joint through an aperture in the capsule (Fig. 6-47).

**Action.** The **subscapularis**, acting with the other scapular muscles of the musculotendinous rotator cuff (supraspinatus, infraspinatus, teres minor), gives stability to the shoulder joint by maintaining the humeral head in the glenoid fossa. It especially helps to prevent anterior displacement of the humerus. When the arm is by the side of the body, the subscapularis acts as a medial rotator of the humerus.

**Nerves.** The subscapularis is supplied by the upper and lower subscapular nerves from the brachial plexus, containing fibers from the fifth and sixth cervical nerves.

**SUPRASPINATUS FASCIA.** The supraspinatus fascia completes the osseofibrous sheath in which the supraspinatus muscle is contained. It affords attachment, on its deep surface, to some of the fibers of the muscle. The fascia is thick medially, but thinner laterally under the coracoacromial ligament.

**THE SUPRASPINATUS.** This muscle occupies the whole of the supraspinatus fossa, arising from its medial two-thirds and from the strong supraspinatus fascia (Fig. 6-46). The muscular fibers converge to form a tendon that crosses the upper part of the shoulder joint, deep to the acromion, and is inserted into the highest of the three impressions on the greater tubercle of the humerus. The tendon is closely adherent to the tendon of the infraspinatus and to the capsule of the shoulder joint.

**Action.** The supraspinatus, with the other muscles forming the rotator cuff, especially strengthens the shoulder joint by drawing the humerus toward the glenoid fossa. Along with the deltoid, the supraspinatus assists and, perhaps, initiates abduction of the arm, and it is also a lateral rotator of the humerus.

**Nerve.** The supraspinatus is supplied by branches of the **suprascapular nerve** from the brachial plexus that contain fibers from the fifth cervical nerve.

**INFRASPINATUS FASCIA.** This fascia is a dense fibrous membrane that covers the infraspinatus muscle and is fixed to the circumference of the infraspinatus fossa. It affords attachment, by its deep surface, to some fibers of that muscle and is intimately attached to the deltoid fascia along the overlapping border of the deltoid muscle.

**THE INFRASPINATUS.** This thick triangular muscle occupies most of the infraspinatus fossa (Fig. 6-46). It arises by fleshy fibers from the medial two-thirds of the fossa and by tendinous fibers from the ridges on its

**FIG. 6-46.** Muscles on the posterior aspect of the scapula, and the triceps brachii, showing the quadrangular, a, and triangular, b, spaces between the two teres muscles.

surfaces. It also arises from the infraspinatus fascia, which covers the muscle and separates it from the teres major and minor. The fibers converge to form a tendon that glides over the lateral border of the spine of the scapula and, passing across the posterior part of the capsule of the shoulder joint, is inserted into the middle impression on the greater tubercle of the humerus, where it is sometimes fused with its neighbors. The tendon of this muscle is sometimes separated from the capsule of the shoulder joint by a bursa, which may communicate with the joint cavity.

**Action.** The *infraspinatus*, as one of the muscles forming the rotator cuff, helps to stabilize the shoulder joint by bracing the head of the humerus in the glenoid fossa. It is also a lateral rotator of the humerus.

**Nerve.** The *infraspinatus* is supplied by the *suprascapular nerve* from the brachial plexus, which contains fibers from the fifth and sixth cervical nerves.

**TERES MINOR.** The *teres minor* is a cylindrical, elongated muscle that arises from the upper two-thirds of the dorsal surface of the lateral or axillary border of the scapula and from two aponeurotic laminae, one of which separates it from the *infraspinatus*, the other from the *teres major* (Fig. 6-46). Its fibers course obliquely upward and laterally. The upper fibers end in a tendon that is inserted into the most inferior of the three impressions on the greater tubercle of the humerus, and the lower fibers are inserted directly into the humerus immediately distal to this impression. The tendon of this muscle passes across, and is united with, the posterior part of the capsule of the shoulder joint.

**Action.** The *teres minor* rotates the arm laterally and weakly adducts it. As do the other muscles forming the rotator cuff, it draws the humerus toward the glenoid fossa, strengthening the shoulder joint.

**Nerve.** The *teres minor* is supplied by a branch of the *axillary nerve*, which comes from the posterior cord of the brachial plexus and contains fibers from the fifth cervical root.

**Variations.** The *teres minor* is sometimes inseparable from the *infraspinatus*.

**TERES MAJOR.** The *teres major* is a thick but somewhat flattened muscle that arises from the oval area on the dorsal surface of the inferior angle of the scapula and from

the fibrous septa interposed between the muscle and the *teres minor* and *infraspinatus*. The fibers are directed superiorly and laterally and end in a flat tendon, about 5 cm long, which is inserted into the medial lip of the intertubercular sulcus of the humerus. The tendon, at its insertion, lies beneath that of the *latissimus dorsi*, from which it is separated by a bursa (Fig. 6-47), except where the two tendons unite along their lower borders for a short distance.

**Action.** The *teres major* adducts as well as assists in extending the arm when it is in a flexed position. It is also a medial rotator. In function it is opposite to those muscles inserting into the rotator cuff.

**Nerve.** The *teres major* is supplied by a branch of the *lower subscapular nerve* from the brachial plexus, containing fibers from the fifth and sixth cervical nerves.

**Group Action of Muscles About the Shoulder.** *Flexion of the arm* is brought about by the anterior part of the *deltoid*, *coracobrachialis*, and short head of the *biceps*, acting at the shoulder joint, and by the *trapezius* and *serratus anterior* rotating the inferior angle of the scapula laterally on the posterior thoracic wall to raise the point of the shoulder. The clavicular part of the *pectoralis major* also assists in flexion until the arm is raised above the shoulder.

*Extension of the arm* is brought about by the *latissimus dorsi*, acting on both the shoulder joint and the scapula, and it is strongly assisted by the sternocostal part of the *pectoralis major* except in hyperextension. The *teres major*, posterior *deltoid*, and long head of the *triceps* extend the arm at the shoulder joint. The *scapula is protracted* (rotated forward and downward) by the *pectoralis minor* and *retracted* (drawn backward) by the *rhomboids* and *trapezius*.

*Abduction of the arm* is carried out by the *deltoid* and *supraspinatus*, acting on the shoulder joint, and by the *trapezius* and *serratus anterior* rotating the scapula to raise the shoulder.

*Adduction of the arm* is performed principally by the *pectoralis major* and *latissimus dorsi*, and by the *coracobrachialis* and *teres major* acting on the shoulder joint, by the *pectoralis minor* protracting the scapula, and by the lower portion of the *trapezius*, which draws the scapula downward.

*Medial rotation of the humerus* is brought about primarily by the *subscapularis* and *teres major* when it is performed as a voluntary act, but the *pectoralis major* and *latissimus dorsi* have strong medial rotating power incidental to their contraction.

*Lateral rotation of the humerus* is performed by the *infraspinatus*, *supraspinatus*, and *teres minor*.

Independent movements of the scapula are *elevation* by the *levator scapulae* and upper part of the *trapezius*; *depression* by the *pectoralis minor*, lower *trapezius*, and lower *serratus anterior*; *abduction of*

**FIG. 6-47.** Muscular insertions and bursae around the shoulder joint. (From Rauber-Kopsch, 19th Ed., Vol. 1, Georg Thieme Verlag, Stuttgart.)

the scapula (drawing it forward) by the serratus anterior, as in pushing; *adduction of the scapula* (drawing it backward) by the rhomboids and trapezius.

## MUSCLES OF THE ARM

The arm is defined as that part of the upper limb extending between the shoulder joint and the elbow joint. The arm contains four muscles:

- Coracobrachialis
- Biceps brachii
- Brachialis
- Triceps brachii

**BRACHIAL FASCIA.** The portion of the investing fascia that covers the arm is a strong membrane, but it is not, for the most part, distinctly aponeurotic. It is called the **brachial fascia** and is continuous proximally with the deltoid, pectoral, and axillary fasciae. Attaching distally to the epicondyles of the humerus and the olecranon, the brachial fascia is then continuous with the antebrachial fascia. Beginning at the attachment to the

epicondyles and prolonged proximally into the arm are two intermuscular septa, medial and lateral, which divide the arm into flexor and extensor compartments (Fig. 6-48). The **lateral brachial intermuscular septum** is attached along the lateral supracondylar ridge and is fused with the internal surface of the investing brachial fascia. The septum extends distally to the lateral epicondyle and proximally to the insertion of the deltoid, where it continues into the deltoid fascia. Its posterior surface is used by the triceps for the origin of some of its fibers, while the anterior surface gives origin to some fibers of the brachialis, brachioradialis, and extensor carpi radialis longus. Its distal portion is pierced by the radial nerve and the radial collateral branch of the deep brachial artery. The **medial brachial intermuscular septum** is attached to the medial supracondylar ridge below, and it extends from the medial epicondyle distally to the insertions of the teres major and latissimus dorsi proximally. Some fibers of the triceps originate from its dorsal surface, and some fibers of the brachialis from its ventral surface. It is

FIG. 6-48. Cross section through the middle of the right arm. Viewed from the superior aspect.

pierced near the epicondyle by the ulnar nerve, the superior ulnar collateral artery, and the posterior branch of the inferior ulnar collateral artery. The medial septum appears much thicker than the lateral because the axillary sheath, containing the main vessels and nerves of the arm, blends with its ventral surface, and the nerves and vessels continue this close association down to the elbow. The two intermuscular septa and the investing fascia of the posterior aspect of the arm form the posterior or **extensor compartment**, which contains the triceps, radial nerve, and deep brachial artery (Fig. 6-48). The anterior or **flexor compartment** contains the biceps, the brachialis, part of the coracobrachialis, the brachial vessels, and the median and ulnar nerves.

The relationship of the investing fascia to the muscles is different on the dorsal and ventral aspects of the arm. The fascia over the triceps is adherent to the muscle and is used in part for its origin. In contrast, the fascia over the biceps is separated from the muscle by a distinct fascial cleft which continues around its deep surface, thereby also separating the biceps from the brachialis.

Just below the middle of the arm, the anterior investing fascia is pierced medially by the basilic vein and at several sites by filaments of the brachial cutaneous nerves.

**THE CORACOBRACHIALIS.** The coracobrachialis is the smallest of the three muscles in this region (Figs. 6-45; 6-49). Situated at the upper and medial part of the arm, it arises from the apex of the coracoid process, in common with the short head of the biceps brachii, and from the intermuscular septum between the two muscles. It is inserted by means of a flat tendon into an impression at the middle of the medial surface and border of the body of the humerus between the origins of the triceps brachii and brachialis. It is perforated by the musculocutaneous nerve.

**Action.** The coracobrachialis muscle flexes and adducts the arm.

**Nerve.** The coracobrachialis is supplied by a branch of the **musculocutaneous nerve** that contains fibers from the sixth and seventh cervical nerves.

**Variations.** The most frequent variation in the attachment of the coracobrachialis is for the most

superficial portion to reach as far as the medial epicondyle. More rarely a short head is found inserting on the lesser tubercle.

**BICEPS BRACHII.** The biceps brachii is a long fusiform muscle, placed on the anterior aspect of the arm, that consists of two heads, a fact implied by its name (Figs. 6-45; 6-48; 6-49). The **short head** arises by a thick flattened tendon from the apex of the coracoid process, in common with the coracobrachialis. The **long head** arises within the capsule of the shoulder joint from the supraglenoid tuberosity at the upper margin of the glenoid cavity, and is continuous with the glenoidal labrum. This tendon, enclosed in a

special sheath of the synovial membrane of the shoulder joint, arches over the head of the humerus. It emerges from the capsule through an opening between the two tubercles, deep to the transverse humeral ligament, and descends in the intertubercular sulcus. It is retained in the sulcus by the transverse humeral ligament and by a fibrous prolongation from the tendon of the pectoralis major. The tendon of each head is succeeded by an elongated muscular belly, and the two bellies, although closely applied to each other, can readily be separated down to about 7 cm above the elbow joint. Here they end in a flattened tendon, which is inserted into the rough posterior surface of the

**FIG. 6-49.** Muscles of the right shoulder and arm, viewed from the anterior aspect. Note that the pectoralis major and minor muscles have been cut near their insertions to reveal the underlying structures. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, Urban & Schwarzenberg, 11th Ed., Vol. 1, 1975.)

tuberosity of the radius, a bursa being interposed between the tendon and the anterior part of the tuberosity. As the tendon of the muscle approaches the radius it is twisted, so that its anterior surface becomes lateral at its insertion to the tuberosity of the radius. Opposite the bend of the elbow the tendon gives off a broad aponeurosis from its medial side, the **bicipital aponeurosis** (*lacertus fibrosus*), which passes obliquely downward and medially across the brachial artery and is continuous with the deep fascia covering the origins of the flexor muscles of the forearm (Fig. 6-49).

**Action.** When the forearm is partially flexed, the **biceps brachii** is a powerful supinator of the forearm. This action is less powerful when the forearm is extended. It is also an important flexor of the supinated forearm, and upon continued action, it can flex, although not so powerfully, the arm at the shoulder joint. The biceps does not appear to act as a flexor of the pronated forearm.

One can conceive of the action of the biceps in the use of a screwdriver, placed in the right hand and turning a screw in a clockwise manner. It has also cleverly been described as the muscle that puts in the corkscrew and pulls out the cork. The tendon of the long head also helps to prevent the elevation of the head of the humerus during abduction by the deltoid.

**Nerves.** The biceps brachii is supplied by branches of the **musculocutaneous nerve** that contain fibers from the fifth and sixth cervical nerves.

**Variations.** A third head to the biceps brachii frequently is noted (10%), arising at the upper and medial part of the brachialis. Its fibers are continuous with those of the brachialis and are inserted into the bicipital fascia and medial side of the tendon of that muscle. In most cases, this additional slip lies deep to the brachial artery in its course down the arm. In some instances the third head consists of two slips, which pass downward, one superficial and the other deep to the artery, concealing the vessel in the lower half of the arm. More rarely, a fourth head is seen arising from the lateral aspect of the humerus, from the intertubercular groove, or from the greater tubercle. Other heads are occasionally found. Slips sometimes pass from the inner border of the muscle over the brachial artery to the medial intermuscular septum or the medial epicondyle, or more rarely to the pronator teres or brachialis. The long head may be absent or may arise from the intertubercular groove.

**THE BRACHIALIS.** The brachialis muscle covers the lower half of the humerus and the anterior aspect of the elbow joint (Figs. 6-45; 6-48; 6-49). It arises from the distal half of the anterior surface of the humerus, commenc-

ing at the insertion of the deltoid, which it embraces by two angular processes. Its origin extends distally to within 2.5 cm of the margin of the articular surface of the elbow joint. It also arises from the intermuscular septa, but more extensively from the medial than the lateral. Distally, it is separated from the lateral intermuscular septum by the brachioradialis and extensor carpi radialis longus. Its fibers converge to a thick tendon, which is inserted into the tuberosity of the ulna and the rough depression on the anterior surface of the coronoid process.

**Action.** The **brachialis** is a powerful flexor of the forearm.

**Nerve.** The brachialis is supplied by a branch of the **musculocutaneous nerve**, containing fibers from the fifth and sixth cervical nerves. Usually a small branch of the radial nerve supplies some of the lateral part of the muscle; this may be a sensory nerve.

**Variations.** Occasionally the brachialis may be doubled or, more rarely, additional muscular slips to the supinator, pronator teres, biceps, bicipital fascia, or radius are found.

**TRICEPS BRACHII.** The triceps is situated on the dorsal aspect of the arm within the extensor compartment and extends along the entire length of the dorsal surface of the humerus (Figs. 6-46; 6-48). It is a large muscle that arises by three heads: long, lateral, and medial, hence its name.

The **long head** arises by a flattened tendon from the infraglenoid tuberosity of the scapula. It is blended proximally with the capsule of the shoulder joint. The muscle fibers pass downward between the two other heads of the muscle, joining them in the tendon of insertion.

The **lateral head** arises from the posterior surface of the body of the humerus, between the insertion of the teres minor and the proximal part of the oblique groove for the radial nerve, and from the lateral border of the humerus and the lateral intermuscular septum. From this origin, the fibers converge toward the tendon of insertion.

The **medial head**, which really might be considered the deep head, arises from the posterior surface of the body of the humerus, distal to the groove for the radial nerve. It also arises from the medial border of the humerus and from the whole length of the medial intermuscular septum. The medial head is narrow and pointed proximally, and it extends from the insertion of the teres

major to within 2.5 cm of the trochlea. Some of the fibers are directed downward to the olecranon, while others converge to the tendon of insertion.

The tendon of the triceps begins about the middle of the muscle. It consists of two aponeurotic laminae, one of which is immediately subcutaneous and covers the superficial surface of the distal half of the muscle, and the other more deeply seated in the substance of the muscle. After receiving the attachment of the muscular fibers, the two tendinous layers join a short distance above the elbow, and are inserted, for the most part, into the posterior portion of the proximal surface of the olecranon. A band of fibers is continued downward, on the lateral side, over the anconeus muscle to blend with the deep fascia of the forearm.

**Triangular and Quadrangular Spaces.** The long head of the triceps descends between the teres minor and teres major, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular and the other quadrangular (Fig. 6-46). The **triangular space** transmits the scapular circumflex vessels. It is bounded *superiorly* by the teres minor; *inferiorly*, by the teres major; and *laterally*, by the long head of the triceps. The **quadrangular space** transmits the posterior humeral circumflex vessels and the axillary nerve. *Superiorly*, it is bounded by the teres minor and capsule of the shoulder joint; *inferiorly*, by the teres major; *medially*, by the long head of the triceps; and *laterally*, by the humerus.

**Action.** All three heads of the **triceps brachii** extend the forearm at the elbow joint. The long and lateral heads are especially active against resistance. The long head, arising from the scapula, is also able to extend the humerus at the shoulder joint.

**Nerves.** The triceps brachii is supplied by branches of the **radial nerve** that contain fibers from the seventh and eighth cervical nerves.

**Variations.** At times this muscle receives a fourth head from the inner part of the humerus. A muscular slip, the **dorsoepitrochlearis brachii** at times extends from the latissimus dorsi to the long head of the triceps.

**Articularis Cubiti.** Also called the subanconeus, this structure consists only of a few fibers that spring from the deep surface of the lower part of the triceps and are inserted into the posterior aspect of the articular capsule of the elbow joint.

## MUSCLES OF THE FOREARM

**ANTEBRACHIAL FASCIAE.** The portion of the investing fascia that covers the proximal forearm is a strong aponeurotic sheet, closely adherent to the underlying muscles

(Fig. 6-50). Proximally, it is continuous with the brachial fascia and is attached to the epicondyles of the humerus and the olecranon. Distally, it is attached to the lower portions of the radius and ulna and is continued into the fascia of the hand. It is attached to the dorsal border of the ulna through most of its length, closing off the flexor and extensor compartments of the forearm. In the proximal two-thirds of the forearm, the underlying muscles utilize the deep surface of the investing fascia for attachment of some muscle fibers. The fascia also extends deep between the muscles toward the radius and ulna, forming strong intermuscular septa which also allow attachment of muscle fibers. The anterior or volar aspect of the antebrachial fascia is visibly thickened by collagenous bundles derived from the tendon of the biceps, which fans out medially as an aponeurosis of the biceps brachii muscle. On the posterior aspect of the forearm, the fascia is even thicker, receiving similar collagenous bundles from the triceps tendon. Near the distal ends of the radius and ulna, the fascia is abruptly thickened by the addition of prominent, annular, collagenous bundles, which form the **flexor and extensor retinacula**. In the distal third of the forearm, the muscles and tendons are separated from the overlying fascia by fascial clefts, whereas more proximally, the fascia adheres to the underlying muscle tissue. The antebrachial fascia is pierced in several places by vessels and nerves. The largest aperture, anterior to the elbow, is penetrated by the branch of the median cubital vein that communicates with the deep veins in the antecubital fossa. The radius, ulna, and interosseous membrane form a septum dividing the forearm into an anterior flexor and a posterior extensor compartment.

In the **extensor compartment**, an intermuscular fascial cleft separates the superficial from the deep muscles, especially near the wrist, but it is closed medially and laterally and does not communicate with other clefts. In the **flexor compartment**, the intermuscular fascial cleft is more extensive and may communicate with the fascial clefts of the palm. This cleft is especially prominent between the anterior surface of the pronator quadratus and the overlying muscles and tendons, and at this site it is called the **anterior interosseous cleft**. It continues proximally between the flexors digitorum profundus and superficialis and may follow

**Fig. 6-50.** Transverse section through the middle of the right forearm, viewed from above.

along the ulnar vessels and nerve to the antecubital fossa. At the wrist, the anterior interosseous cleft continues distally deep to the flexor tendon sheaths to communicate with the middle palmar cleft of the hand. The antebrachial or forearm muscles may be divided into an **anterior group**, which occupies the flexor compartment, and a **posterior group** in the extensor compartment.

### **Anterior Antebrachial Muscles**

These muscles are divided for convenience of description into two groups, superficial and deep.

#### **SUPERFICIAL FLEXOR GROUP**

Pronator teres  
Flexor carpi radialis  
Palmaris longus  
Flexor carpi ulnaris  
Flexor digitorum superficialis

The superficial group of anterior antebrachial muscles forms the rounded contour

on the medial aspect of the upper forearm (Fig. 6-51). They take origin from the medial epicondyle of the humerus by a common tendon, and from the deep fascia of the forearm near the elbow, as well as from the septa, which pass from this fascia between the individual muscles.

**PRONATOR TERES.** The pronator teres has two heads of origin, humeral and ulnar (Fig. 6-51). The **humeral head**, larger and more superficial, arises immediately above the medial epicondyle, and also from the tendon common to the origin of the flexor muscles, from the intermuscular septum between it and the flexor carpi radialis, and from the antebrachial fascia. The **ulnar head** is a thin fasciculus that arises from the medial side of the coronoid process of the ulna and joins the humeral head at an acute angle. The median nerve enters the forearm between the two heads of the muscle and is separated from the ulnar artery by the ulnar head. The muscle passes obliquely across the forearm and ends in a flat tendon that is inserted on a rough impression about mid-

**FIG. 6-51.** Anterior aspect of left forearm. Superficial muscles.

way along the lateral surface of the body of the radius. The lateral border of the pronator teres forms the medial boundary of a triangular hollow, the **cubital fossa**, situated on the anterior aspect of the upper extremity in front of the elbow joint. Among other structures, the fossa contains the median cubital vein, the brachial artery, the median nerve, and the tendon of the biceps muscle.

**Action.** The **pronator teres** rotates the radius on the ulna, thereby pronating the forearm and the

hand. It also assists in flexing the forearm at the elbow joint.

**Nerve.** The pronator teres is supplied by a branch of the **median nerve** that contains fibers from the sixth and seventh cervical nerves.

**Variations.** At times the ulnar head may be absent. Additional slips may be derived from the medial intermuscular septum, the biceps, and occasionally from the brachialis muscle.

**FLEXOR CARPI RADIALIS.** The flexor carpi radialis lies on the medial or ulnar side of the pronator teres (Figs. 6-50; 6-51). It arises from the medial epicondyle by the common flexor tendon, from the antebrachial fascia, and from the intermuscular septa between it and the pronator teres laterally, the palmaris longus medially, and the flexor digitorum superficialis which lies beneath. The muscle is slender and aponeurotic in structure at its origin; it increases in size and ends in a tendon a little more than halfway down the forearm. The tendon passes through a canal in the lateral part of the flexor retinaculum and courses along a groove on the trapezium, which becomes converted into a canal by fibrous tissue and is lined by a synovial sheath. The tendon is inserted into the base of the second metacarpal bone and sends a slip to the base of the third metacarpal bone. In the distal part of the forearm, the radial artery lies between the tendon of the flexor carpi radialis and the brachioradialis.

**Action.** The **flexor carpi radialis** flexes the hand at the wrist joint and helps to abduct (radially flex) it.

**Nerve.** The flexor carpi radialis is supplied by a branch of the **median nerve**, containing fibers from the sixth and seventh cervical nerves.

**Variations.** Occasionally slips from the tendon of the biceps, the bicipital fascia, the coronoid, and the radius have been found extending to the flexor carpi radialis. Its insertion often varies and may be extended to the trapezium or the fourth metacarpal. The muscle may be absent.

**PALMARIS LONGUS.** The palmaris longus is a slender, fusiform muscle lying on the medial aspect of the flexor carpi radialis (Figs. 6-50; 6-51). It arises from the medial epicondyle of the humerus by the common flexor tendon, from the intermuscular septa between it and the adjacent muscles, and from the antebrachial fascia. It ends in a slender, flattened tendon, which passes superficial to the flexor retinaculum and is inserted into

the anterior aspect of the distal part of the flexor retinaculum and into the palmar aponeurosis; it frequently sends a tendinous slip to the short muscles of the thumb.

**Action.** The *palmaris longus* flexes the hand at the wrist.

**Nerve.** The *palmaris longus* is innervated by a branch of the *median nerve*, containing fibers from the sixth and seventh cervical nerves.

**Variations.** The *palmaris longus* is one of the most variable muscles in the body and is often (10%) absent. It may be tendinous proximally and muscular distally, or it may be muscular in the center with a tendon above and below. It may present two muscular bundles with a central tendon and might even consist solely of a tendinous band. The muscle may be doubled. Slips of origin from the coronoid process or from the radius have been seen. Partial or complete insertion into the antebrachial fascia, into the tendon of the flexor carpi ulnaris and pisiform bone, into the scaphoid, or into the hypothenar muscles has been observed.

**FLEXOR CARPI ULNARIS.** This muscle lies along the ulnar side of the forearm (Figs. 6-50; 6-51). It is formed from two heads, humeral and ulnar, connected by a tendinous arch, beneath which the ulnar nerve descends in the forearm and the posterior ulnar recurrent artery ascends to participate in the anastomosis around the elbow joint. The **humeral head** arises from the medial epicondyle of the humerus by the common flexor tendon. The **ulnar head** arises from the medial margin of the olecranon and from the upper two-thirds of the posterior border of the ulna by an aponeurosis common to it and the extensor carpi ulnaris and flexor digitorum profundus. It also arises from the intermuscular septum between it and the flexor digitorum superficialis. The fibers of the flexor carpi ulnaris end in a tendon that occupies the anterior part of the lower half of the muscle and, prolonged to the hamate and fifth metacarpal bones by the pisohamate and pisometacarpal ligaments, is inserted into the pisiform bone. It is also attached by a few fibers to the flexor retinaculum. Along the distal two-thirds of the forearm, the ulnar vessels and nerve lie on the lateral aspect of the tendon of this muscle.

**Action.** The *flexor carpi ulnaris* flexes and adducts (ulnar flexes) the hand.

**Nerve.** The *flexor carpi ulnaris* is supplied by a

branch of the *ulnar nerve*, containing fibers from the eighth cervical and first thoracic nerves.

**Variations.** Occasionally the muscle receives a slip of origin from the coronoid.

The *epitrochleoanconeus* is a small muscle that is often seen coursing over the ulnar nerve from the back of the medial condyle of the humerus to the medial aspect of the olecranon.

**FLEXOR DIGITORUM SUPERFICIALIS.** The flexor digitorum superficialis lies deep to the other muscles in the superficial flexor group (Figs. 6-50; 6-51). It is the largest of the muscles of the superficial group and is formed from two heads, humeroulnar and radial. The **humeroulnar head** arises from the medial epicondyle of the humerus by the common flexor tendon, from the ulnar collateral ligament of the elbow joint, from the intermuscular septa between it and the preceding muscles, and from the medial aspect of the coronoid process, proximal to the ulnar origin of the pronator teres. The **radial head** is broad but thin. It arises from an oblique line on the anterior surface of the radius, and this line extends from the radial tuberosity to the insertion of the pronator teres. From its origin the flexor digitorum superficialis quickly separates into two planes of muscular fibers, superficial and deep. The *superficial plane* divides into two parts, which end in tendons for the middle and ring fingers. The *deep plane* gives off a muscular slip to join the portion of the superficial plane that is associated with the tendon of the ring finger; it then divides into two parts, which end in tendons for the index and little fingers. As the four tendons thus formed pass beneath the flexor retinaculum into the palm of the hand, they are arranged in pairs, the superficial pair going to the middle and ring fingers, the deep pair to the index and little fingers. The tendons diverge in the palm, passing dorsal to the superficial palmar arch and digital branches of the median and ulnar nerves. Opposite the bases of the first phalanges, each tendon divides into two slips to allow the passage to each finger of the corresponding tendon of the flexor digitorum profundus. The two slips then reunite and form a grooved channel for the reception of the accompanying tendon of the flexor digitorum profundus. Finally, each superficialis tendon divides again to be inserted on the sides of the second phalanx of the corresponding fingers.

**Action.** The *flexor digitorum superficialis* flexes the second phalanx of each finger and, by continued action, flexes the first phalanx at the metacarpophalangeal joint and the hand at the wrist joint.

**Nerves.** The *flexor digitorum superficialis* is supplied by branches of the **median nerve**, containing fibers from the seventh and eighth cervical and first thoracic nerves.

**Variations.** The radial head, or little finger portion, of the *flexor digitorum superficialis* may be absent. Accessory slips may occur from the tuberosity of the ulna to the index and middle finger portions. Another slip may be derived from the humeroulnar head to the *flexor profundus*, and variations occur in the origin of muscular slips to the little finger.

### DEEP FLEXOR GROUP

*Flexor digitorum profundus*  
*Flexor pollicis longus*  
*Pronator quadratus*

**FLEXOR DIGITORUM PROFUNDUS.** The *flexor digitorum profundus* is situated on the ulnar side of the forearm, immediately beneath the superficial flexors (Figs. 6-50; 6-52). It arises from the upper three-fourths of the anterior and medial surfaces of the body of the ulna, embracing the insertion of the *brachialis* above and extending downward to within a short distance of the *pronator quadratus*. It also arises from a depression on the medial aspect of the coronoid process; from the upper three-fourths of the dorsal border of the ulna by way of an aponeurosis in common with the *flexor* and *extensor carpi ulnaris*; and from the ulnar half of the interosseous membrane. The muscle ends in four tendons, which enter the hand beneath the transverse carpal ligament, deep to the tendons of the *flexor digitorum superficialis*. The portion of the muscle for the index finger is usually distinct throughout, but the tendons for the middle, ring, and little fingers are connected by areolar tissue and tendinous slips, as far as the palm of the hand. On the palmar aspect of the first phalanges, the tendons pass through the openings in the tendons of the *flexor digitorum superficialis* to finally become inserted into the bases of the last phalanges. Four small muscles, the *lumbricals*, are connected with the tendons of the *flexor digitorum profundus* in the palm. These will be described with the muscles of the hand.

**FIBROUS SHEATHS OF THE FLEXOR TENDONS.** Distal to the metacarpophalangeal joints, the

FIG. 6-52. Anterior aspect of the left forearm. Deep muscles.

tendons of the flexors digitorum superficialis and profundus lie in strong ligamentous tunnels, the digital **fibrous tendon sheaths**. Each tunnel is lined by a **synovial tendon sheath**, which is a lubricated synovial layer reflected on the contained tendons. Within each digital sheath, the tendons of the superficialis and profundus are connected to each other and to the phalanges by tendinous bands called **vincula tendinum** (Fig. 6-53). There are two types of vincula. (1) The **vincula brevia**, two in number in each finger, are fan-shaped expansions near the termination of the tendons. One connects the superficialis tendon to the palmar surface of the proximal interphalangeal joint and the head of the first phalanx, and the other connects the profundus tendon to the palmar surface of the distal interphalangeal joint and the head of the second phalanx. (2) The **vincula longa** are slender, independent bands that are found in two positions. One pair in each finger connects the deep surface of the pro-

fundus tendon to the subjacent superficialis tendon just distal to the site where the profundus tendon traverses the split in the superficialis tendon. Another pair, or a single vinculum longum, connects the superficialis tendon to the proximal end of the first phalanx.

**Action.** The **flexor digitorum profundus** flexes the terminal phalanx of each finger and, by continued action, flexes the other phalanges and to some extent the hand. This muscle is the largest and most powerful of the forearm muscles.

**Nerves.** The flexor digitorum profundus is supplied by the anterior interosseous branch of the **median nerve** and a branch of the **ulnar nerve**, containing fibers from the eighth cervical and first thoracic nerves.

**Variations.** The index finger portion of the flexor digitorum profundus may arise partly from the proximal portion of the radius. Accessory slips may arise from the humeroulnar head of the flexor superficialis, the medial epicondyle, the coronoid process of the ulna, or the flexor pollicis longus.

**FIG. 6-53.** Tendons of the index finger of the right hand, viewed from the lateral (radial) aspect. Note the vincula longa and brevia.

**FLEXOR POLLICIS LONGUS.** The flexor pollicis longus is situated on the radial side of the forearm, lateral to but on the same plane as the flexor digitorum profundus (Figs. 6-50; 6-52). It arises from the grooved volar surface of the body of the radius, which extends from immediately below the tuberosity and oblique line to within a short distance of the pronator quadratus. It also arises from the adjacent part of the interosseous membrane and, generally, by a fleshy slip from the coronoid process of the ulna or from the medial epicondyle of the humerus. The fibers end in a flattened tendon, which passes deep to the flexor retinaculum, being then lodged between the lateral part of the flexor pollicis brevis and the oblique part of the adductor pollicis. Entering an osseopneurotic canal, similar to those for the flexor tendons of the fingers, the muscle is inserted into the base of the distal phalanx of the thumb. The anterior interosseous (branch of the median) nerve and vessels pass downward in the forearm on the anterior aspect of the interosseous membrane between the flexor pollicis longus and flexor digitorum profundus.

**Action.** The flexor pollicis longus flexes the second phalanx of the thumb and, by continued action, may flex the first phalanx at the metacarpophalangeal joint.

**Nerve.** The flexor pollicis longus is supplied by the anterior interosseous branch of the **median nerve**, containing fibers from the eighth cervical and first thoracic nerves.

**Variations.** The flexor pollicis longus may be connected by additional muscular slips to the flexor superficialis or profundus, or to the pronator teres. An additional tendon to the index finger is sometimes found.

**PRONATOR QUADRATUS.** This flat, small, quadrilateral muscle extends across the anterior aspect of the distal parts of the radius and ulna (Fig. 6-52). It arises from the medial aspect of the anterior surface along the distal one-fourth of the ulna and from an oblique ridge marking this part of the bone. It also arises from a strong aponeurosis that covers the medial third of the muscle. The fibers pass laterally and slightly downward, to be inserted into the distal fourth of the lateral border and anterior surface of the shaft of the radius. The deeper fibers of the muscle are inserted into a triangular area above the ulnar notch of the radius.

**Action.** The pronator quadratus is the principal pronator of the hand. It is assisted by the pronator teres when additional power is required to pronate the hand against resistance (Basmajian and Travill, 1961).

**Nerve.** The pronator quadratus is supplied by the anterior interosseous branch of the **median nerve**, containing fibers from the eighth cervical and first thoracic nerves.

**Variations.** The muscle may split into two or three layers, or it may have increased attachments proximally or distally.

### Posterior Antebrachial Muscles

These muscles are divided for convenience of description into two groups, superficial and deep.

#### SUPERFICIAL EXTENSOR GROUP

Brachioradialis  
Extensor carpi radialis longus  
Extensor carpi radialis brevis  
Extensor digitorum  
Extensor digiti minimi  
Extensor carpi ulnaris  
Anconeus

**THE BRACHIORADIALIS.** The brachioradialis is the most superficial muscle on the radial side of the forearm (Figs. 6-50; 6-54). It arises from the upper two-thirds of the lateral supracondylar ridge of the humerus, between the brachialis and triceps muscles, and from the lateral intermuscular septum. Interposed between the brachioradialis and the brachialis are the radial nerve and the anastomosis between the radial collateral branch of the profunda artery and the radial recurrent artery. The muscle fibers end above the middle of the forearm in a flat tendon, which is inserted into the lateral side of the base of the styloid process of the radius. The tendon is crossed near its insertion by the tendons of the abductor pollicis longus and extensor pollicis brevis. On its ulnar side is the radial artery.

**Action.** Embryologically, the brachioradialis develops with the extensor muscles and is, in fact, even supplied by the radial nerve. However, it acts as a *flexor of the forearm* at the elbow joint. This action is especially evident when the forearm is semipronated and flexion is carried out against resistance. The brachioradialis usually does not act when the forearm is supinated or the flexion is not intense.

**FIG. 6-54.** Posterior aspect of the forearm and hand. Superficial muscles.

**Nerve.** The brachioradialis is supplied by a branch of the **radial nerve**, containing fibers from the fifth and sixth cervical nerves.

**Variations.** The brachioradialis may fuse with the brachialis. Its tendon of insertion may be divided into two or three slips, and the muscle may partially or completely insert into the middle of the radius. Additional muscular slips may extend to the tendon of the biceps, the tuberosity or oblique line of the radius, the extensor carpi radialis longus, or the abductor pollicis longus. The muscle may be absent. In rare instances it is doubled.

**EXTENSOR CARPI RADIALIS LONGUS.** This muscle is placed partly deep to the brachioradialis (Figs. 6-50; 6-54). It arises in line with the brachioradialis from the distal third of the lateral supracondylar ridge of the humerus, from the lateral intermuscular septum, and by a few fibers from the common tendon of origin of the extensor muscles of the forearm. The muscle fibers end at the upper third of the forearm in a flat tendon, which runs along the lateral border of the radius, beneath the abductor pollicis longus and extensor pollicis brevis. It then passes deep to the extensor retinaculum, where it lies in a groove with the extensor carpi radialis brevis on the back of the radius, immediately behind the styloid process. It is inserted into the dorsal surface of the base of the second metacarpal bone, on its radial side (Fig. 6-53).

**Action.** The **extensor carpi radialis longus** is capable of extending and abducting the hand at the wrist joint. This muscle, however, usually acts as a synergist during flexion of the fingers. Its effectiveness as an extensor of the hand becomes appreciated when a quick, intense extensor action is required. It is thought that this muscle, like the brachioradialis, is capable of flexing the forearm, although weakly.

**Nerve.** The extensor carpi radialis longus is supplied by a branch of the **radial nerve** that contains fibers from the sixth and seventh cervical nerves.

**EXTENSOR CARPI RADIALIS BREVIS.** This muscle is shorter, thicker, and partially covered by the extensor carpi radialis longus (Figs. 6-50; 6-54). It arises from the lateral epicondyle of the humerus, by a tendon common to it and other extensor muscles, from the radial collateral ligament of the elbow joint, from a strong aponeurosis which covers its surface, and from the intermuscular septa between it and the adjacent muscles. The fibers end about the middle of

the forearm in a flat tendon, which is closely connected with that of the extensor carpi radialis longus and accompanies it to the wrist. Passing beneath the abductor pollicis longus and extensor pollicis brevis, and then beneath the extensor retinaculum, it is inserted into the dorsal surface of the base of the third metacarpal bone on its radial side. Under the extensor retinaculum the tendon lies on the dorsum of the radius in a shallow groove, to the ulnar side of that which lodges the tendon of the extensor carpi radialis longus and separated from it by a faint ridge. The tendons of both the extensor carpi radialis longus and brevis pass through the same compartment of the dorsal carpal ligament in a single synovial sheath.

**Action.** The **extensor carpi radialis brevis** extends the hand and may also abduct (radially flex) the hand at the wrist joint.

**Nerve.** The extensor carpi radialis brevis is supplied by a branch of the **radial nerve**, containing fibers from the sixth and seventh cervical nerves.

**Variations.** The extensor carpi radialis longus and brevis may split into two or three tendons of insertion to the second and third or even the fourth metacarpal. The two muscles may form a single belly with two tendons. Cross slips between the two muscles may occur.

The **extensor carpi radialis intermedius** rarely arises as a distinct muscle from the humerus, but is not uncommon as an accessory slip from one or both muscles to the second or third or both metacarpals.

The **extensor carpi radialis accessorius** is occasionally found arising from the humerus with or below the extensor carpi radialis longus and inserted into the first metacarpal, or attached to the abductor pollicis brevis, the first dorsal interosseous, or elsewhere.

**EXTENSOR DIGITORUM.** The extensor digitorum is the common extensor of the fingers. Lying centrally in the posterior forearm (Figs. 6-50; 6-54), it arises from the lateral epicondyle of the humerus by the common extensor tendon, from the intermuscular septa between it and the adjacent muscles, and from the antebrachial fascia. It divides distally into four tendons, which pass, together with that of the extensor indicis, through a separate compartment deep to the extensor retinaculum, within a synovial sheath. The tendons then diverge on the back of the hand, each going to a different finger where it is inserted into the middle and distal phalanges. The tendon to the

index finger is accompanied by the extensor indicis, which lies on its ulnar side. As the tendons to the middle, ring, and little fingers descend along the dorsum of the hand, they are fastened together by three bands called the **intertendinous connections**. Occasionally the tendon of the index finger is connected to that of the middle finger by a thin transverse band.

Opposite the metacarpophalangeal joint, each tendon is bound by fibrous tissue to the collateral ligaments and thereby serves as the dorsal ligament of this joint. Beyond the metacarpophalangeal joint, each tendon spreads out into a broad aponeurosis that covers the dorsal surface of the first phalanx. These are called the **extensor hoods** and are reinforced by the tendons of the interossei and lumbrical muscles. Opposite the proximal interphalangeal joint, this aponeurosis divides into three slips, an intermediate and two collateral. The intermediate slip is inserted into the base of the middle phalanx. The two collateral slips continue distally along the sides of the middle phalanx, unite by their contiguous margins, and are inserted into the dorsal surface of the distal phalanx. As the tendons cross the interphalangeal joints, they furnish them with dorsal ligaments.

**Action.** The primary action of the **extensor digitorum** is extension of the fingers as in opening the clenched fist. In addition, it abducts the index, ring, and little finger in a spreading action away from the middle finger. Upon continued action this muscle can also extend the hand at the wrist.

**Nerve.** The extensor digitorum is supplied by a branch of the deep **radial nerve**, containing fibers from the sixth, seventh, and eighth cervical nerves.

**Variations.** An increase or decrease in the number of tendons is common, and an additional slip to the thumb is sometimes present.

**EXTENSOR DIGITI MINIMI.** The extensor digiti minimi is a slender muscle placed on the medial side of the extensor digitorum, with which it is generally connected (Figs. 6-50; 6-54). It arises from the common extensor tendon by a thin tendinous slip and from the intermuscular septa between it and the adjacent muscles. The muscle descends in the forearm between the extensor digitorum and the extensor carpi ulnaris and ends in a tendon that courses through a compartment of the extensor retinaculum dorsal to the distal radioulnar joint. The tendon divides into

two as it crosses the hand, and finally joins the extensor hood and the tendon of the extensor digitorum on the dorsum of the first phalanx of the little finger.

**Action.** The **extensor digiti minimi** extends the little finger and, upon continued action, can aid in extending the hand at the wrist.

**Nerve.** The extensor digiti minimi is innervated by a branch of the **deep radial nerve**, containing fibers from the sixth, seventh, and eighth cervical nerves.

**Variations.** An additional fibrous slip may be found from the lateral epicondyle. The tendon of insertion may not divide, or it may send a slip to the ring finger. The muscle may be fused with the extensor digitorum, but its complete absence is rare.

**EXTENSOR CARPI ULNARIS.** The extensor carpi ulnaris lies on the ulnar side of the forearm (Figs. 6-50; 6-54). It arises from the common extensor tendon on the lateral epicondyle of the humerus, from the dorsal border of the ulna by way of an aponeurosis in common with the flexor carpi ulnaris and the flexor digitorum profundus, and from the deep fascia of the forearm. It ends in a tendon that lies in a groove between the head and styloid process of the ulna, passing through a separate compartment of the extensor retinaculum. The tendon is inserted onto the prominent tubercle at the ulnar side of the base of the fifth metacarpal bone.

**Action.** The **extensor carpi ulnaris** extends and adducts the hand. Similar to the extensors carpi radialis longus and brevis, it also acts as a synergist to the flexors of the fingers, keeping the wrist extended in order to give additional strength in maintaining a clenched fist or in grasping objects with the hand.

**Nerve.** The extensor carpi ulnaris is supplied by a branch of the **deep radial nerve**, containing fibers from the sixth, seventh, and eighth cervical nerves.

**Variations.** In many cases a slip is continued from the insertion of the tendon anteriorly over the opponens digiti minimi to the fascia covering that muscle, the fifth metacarpal bone, the capsule of the fifth metacarpophalangeal articulation, or the proximal phalanx of the little finger. This slip may be replaced by a muscular fasciculus arising from or near the pisiform. It may also insert partially onto the fourth metacarpal bone. The muscle may at times be reduced to a tendinous band, or it may be doubled.

**THE ANCONEURUS.** This small triangular muscle, which lies on the dorsum of the elbow joint, appears to be a continuation of

the triceps brachii (Fig. 6-54). It arises by a separate tendon from the dorsal part of the lateral epicondyle of the humerus. Its fibers diverge and are inserted into the lateral aspect of the olecranon and into the upper one-fourth of the dorsal surface of the body of the ulna.

**Action.** The **anconeus** assists in extending the forearm.

**Nerves.** The anconeus is supplied by a branch of the **radial nerve** that contains fibers from the seventh and eighth cervical nerves.

## DEEP EXTENSOR GROUP

Supinator  
Abductor pollicis longus  
Extensor pollicis brevis  
Extensor pollicis longus  
Extensor indicis

**THE SUPINATOR.** The supinator, a broad muscle, is curved around the upper one-third of the radius. It consists of two planes

FIG. 6-55. The supinator muscle.

**Fig. 6-56.** Posterior aspect of the forearm. Deep muscles.

of fibers, between which the deep branch of the radial nerve lies (Figs. 6-55; 6-56). The two planes arise in common—the superficial one by tendinous and the deeper by muscular fibers—from the lateral epicondyle of the humerus, from the radial collateral ligament

of the elbow joint and the annular ligament of the proximal radioulnar joint, from the supinator crest on the ulna, which runs obliquely downward from the dorsal end of the radial notch, from a triangular depression distal to the notch, and from a tendinous aponeurosis that covers the surface of the muscle. The superficial fibers surround the upper part of the radius and are inserted into the lateral edge of the radial tuberosity and the oblique line of the radius, as far down as the insertion of the pronator teres. The proximal fibers of the deeper plane encircle the neck of the radius to the radial tuberosity and are inserted onto the back part of its medial surface. The greater part of the deep portion of the muscle is inserted onto the dorsal and lateral aspects of the upper third of the radial shaft.

**Action.** As its name implies, the **supinator** rotates the radius to supinate the forearm and hand. It is not as powerful as the biceps in this action but it is effective whether the forearm is flexed or extended, whereas the biceps principally supinates the flexed forearm.

**Nerve.** The supinator is supplied by the **deep branch of the radial nerve**, containing fibers from the sixth cervical nerve.

**ABDUCTOR POLLICIS LONGUS.** The abductor pollicis longus lies immediately below the supinator (Fig. 6-56) and is sometimes united with it. It arises from the lateral part of the posterior surface of the body of the ulna distal to the insertion of the anconeus, from the interosseous membrane, and from the middle third of the posterior surface of the body of the radius. Passing obliquely downward and laterally, it ends in a tendon that courses through a groove on the lateral side of the lower end of the radius, accompanied by the tendon of the extensor pollicis brevis. It is inserted into the radial side of the base of the first metacarpal bone (Fig. 6-53). It usually gives off two slips near its insertion: one to the trapezium and the other to blend with the origin of the abductor pollicis brevis.

**Action.** The primary action of the **abductor pollicis longus** is a combined abduction and extension of the thumb at the carpometacarpal joint. It is also an important abductor (radial flexor) of the wrist, and its insertion allows it also to help in *flexing* the wrist.

**Nerve.** The abductor pollicis longus is supplied

by the posterior interosseous branch of the **deep radial nerve**, containing fibers from the sixth and seventh cervical nerves.

**EXTENSOR POLLICIS BREVIS.** The extensor pollicis brevis lies medial to and contiguous with the abductor pollicis longus (Fig. 6-56). It arises from the posterior surface of the body of the radius below the abductor pollicis longus, and from the interosseous membrane. Its direction is similar to that of the abductor pollicis longus, and its tendon passes through the same groove on the lateral side of the distal end of the radius. It is inserted into the base of the first phalanx of the thumb (Fig. 6-53).

**Action.** The **extensor pollicis brevis** extends the proximal phalanx at the metacarpophalangeal joint of the thumb. By continued action it can extend the first metacarpal bone at the carpometacarpal joint. It can also radially flex (abduct) the hand at the wrist.

**Nerve.** The **extensor pollicis brevis** is supplied by the posterior interosseous branch of the **deep radial nerve**, containing fibers from the sixth and seventh cervical nerves.

**Variations.** At times this muscle is absent, or its tendon is fused with that of the **extensor pollicis longus**.

**EXTENSOR POLLICIS LONGUS.** The **extensor pollicis longus** is much larger than the **extensor pollicis brevis**, the origin of which it partly covers (Figs. 6-50; 6-56). It arises from the middle third of the dorsolateral surface of the ulna distal to the origin of the **abductor pollicis longus**, and from the interosseous membrane. It ends in a tendon that passes through a separate compartment in the **extensor retinaculum**, lying in a narrow, oblique groove on the dorsum of the lower end of the radius. It then crosses obliquely the tendons of the **extensor carpi radialis longus** and **brevis**, and is separated from the **extensor pollicis brevis** by a triangular interval, commonly referred to as the "anatomical snuff-box," in which the radial artery is found. Its tendon is finally inserted into the base of the last phalanx of the thumb. The radial artery is crossed by the tendons of the **abductor pollicis longus** and of the **extensors pollicis longus** and **brevis** before it penetrates to the palmar side of the hand between the two heads of the dorsal interosseous muscle.

**Action.** The **extensor pollicis longus** extends the distal phalanx of the thumb and, by continued action, can extend the proximal phalanx and the first metacarpal bone. It also may assist in extension of the hand at the carpometacarpal joint.

**Nerve.** The **extensor pollicis longus** is supplied by the posterior interosseous branch of the **deep radial nerve**, containing fibers from the sixth, seventh, and eighth cervical nerves.

**EXTENSOR INDICIS.** This narrow, elongated muscle is placed medial to, and parallel with, the **extensor pollicis longus**. It arises from the posterior surface of the body of the ulna below the origin of the **extensor pollicis longus**, and from the interosseous membrane. Its tendon passes under the **extensor retinaculum** in the same compartment that contains the tendons of the **extensor digitorum**. Opposite the head of the second metacarpal bone, the tendon of the **extensor indicis** joins the ulnar side of the tendon of the **extensor digitorum** coursing to the index finger, thereby inserting into the **extensor hood** of the second digit.

**Action.** The **extensor indicis** allows extension of the index finger, independent of the other fingers. It assists in adduction of the index finger and can also help in extending the hand at the wrist joint.

**Nerve.** The **extensor indicis** is supplied by the posterior interosseous branch of the **deep radial nerve**, containing fibers from the sixth, seventh, and eighth cervical nerves.

**Variations.** A slip from the tendon of the **extensor indicis** may pass to the middle finger, and the muscle may, at times, be doubled.

**Group Actions of Forearm Muscles.** *Flexion of the wrist joint* is brought about by the **flexor carpi ulnaris**, **flexor carpi radialis**, **palmaris longus**, and **abductor pollicis longus**. If the fingers are kept extended and prevented from flexing, the **flexors digitorum superficialis** and **profundus** can assist in voluntary flexion at the wrist joint.

*Extension at the wrist joint* is performed by the **extensors carpi radialis longus** and **brevis** and by the **extensor carpi ulnaris**. If the fingers are kept flexed as in a clenched fist, the **extensor digitorum** and **extensor pollicis longus** can assist in extension at the wrist joint.

*Abduction (radial flexion) at the wrist joint* principally results from the action of the **abductor pollicis longus** and the **extensor pollicis brevis**; however, the **flexor carpi radialis**, the **extensors carpi radialis longus** and **brevis**, and the **extensor pollicis longus** all assist in this action.

*Adduction (ulnar flexion) at the wrist joint* is performed by the combined action of the **flexor carpi ulnaris** and **extensor carpi ulnaris**.

*Pronation of the hand* is brought about by the pronator quadratus and pronator teres muscles.

*Supination of the hand* is performed by the supinator muscle and more strongly by the biceps brachii muscle.

#### FASCIAE, RETINACULA, TENDON SHEATHS AND COMPARTMENTS OF THE WRIST AND HAND

The tendons of the muscles in the forearm, which attach at the wrist or continue into the hand, along with the descending vessels and nerves, are retained close to bone by strong fascial structures. Additionally, the tendons are surrounded by lubricating synovial sheaths contained within compartments, that serve to further maximize efficiency of function. In the hand, fascial spaces of clinical significance separate the muscle groups and other structures.

##### *Superficial Fascia*

The superficial fascia on the anterior aspect of the forearm changes its character abruptly at the distal crease of the wrist from a delicate movable tissue into the tough cushion that covers the palm and palmar surface of the digits. The superficial fascia of the hand contains a considerable amount of fat, but cannot be separated readily into superficial and deep layers. The adipose tissue is permeated by strong fibrous bands and septa, which divide it into small lobules and bind it securely to the deep fascia as well as to the skin. The dermis is compact; it not only protects the underlying structures, but also offers resistance to the progress of infectious processes seeking to achieve the surface. The vertical direction of the fibrous bands tends to guide the spread of infection into deeper layers. The superficial fascia is adherent to the deep fascia over the entire palm, but the union is especially strong at the skin creases of the wrist, the major creases of the palm, and the creases of the digits. At the medial and lateral borders of the hand and digits, the fascia changes its character rather abruptly as it becomes continuous with the superficial fascia that covers the dorsum of the hand.

The superficial fascia over the dorsum of the hand and fingers is delicate and movable, similar to that of the forearm with which

it is continuous. Its two layers can be identified: the superficial layer is thin but may contain a small amount of fat; the deep layer of superficial fascia is a definite fibrous sheet and supports the superficial veins and cutaneous nerves. It is separated from the deep fascia by a distinct fascial cleft, the **dorsal subcutaneous cleft**, which imparts the characteristic movability to the skin of the back of the hand.

##### *Deep Fascia*

The antebrachial fascia at the wrist is thickened into an annular band or cuff, which holds the tendons of the forearm muscles close against the wrist. This distal portion of the investing antebrachial fascia is strengthened by strong transverse collagenous bundles. It is attached medially and laterally to the styloid processes of the ulna and radius, and it is frequently called the *superficial part of the flexor retinaculum*. At one time it was called the palmar (or volar) carpal ligament, but distally it actually merges with the flexor retinaculum. The ulnar nerve and vessels emerge from beneath this layer of fascia to enter the hand superficial to the flexor retinaculum.

**FLEXOR RETINACULUM.** The flexor retinaculum (Fig. 6-57) is a thick fibrous band that arches over the deep groove on the palmar surface of the carpal bones, forming the **carpal tunnel** through which the long flexor tendons and the median nerve pass. At one time this retinaculum was called the *transverse carpal ligament*. It is attached, medially, to the pisiform and the hamulus of the hamate, and laterally, to the tuberosity of the scaphoid and the medial part of the palmar surface and ridge of the trapezium. Its proximal border is partly merged with the distal portion of the investing antebrachial fascia, but the latter belongs to a different and more superficial stratum and is separated from the flexor retinaculum by the ulnar vessels and nerve. The flexor retinaculum is attached to the palmar aponeurosis, which lies superficial to it, and contributes oblique crossed fibers to the deep surface of the aponeurosis. It has two attachments to the trapezium, one on each side of the groove in which the tendon of the flexor carpi radialis lies. The flexor carpi ulnaris, at its insertion, contributes tendinous fibers to the flexor retinacu-

FIG. 6-57. Synovial and fibrous tendon sheaths on the palmar aspect of the right wrist and hand.

lum; to a large extent, the thenar and hypothenar muscles arise from it.

**EXTENSOR RETINACULUM.** The extensor retinaculum is a strong fibrous band under which the extensor tendons lie (Fig. 6-58). It is the distal portion of the investing antebrachial fascia, which is thickened at the dorsum of the wrist by the addition of transverse collagenous bundles. These take a somewhat oblique course, extending distalward as they cross from the radial to the ulnar side. The retinaculum is attached medially to the styloid process of the ulna and to the triquetral and pisiform bones, and lat-

erally to the lateral margin of the radius. Between these medial and lateral borders, it is attached to the ridges on the dorsal surface of the radius.

### **Tendon Sheaths**

As the forearm tendons descend through the wrist and into the hand and then along the digits, they are encased by synovial sheaths. These tubular structures, which resemble the bursae found at other joints, are formed by inner visceral and outer parietal membranous layers with a potential space

intervening that contains lubricating fluid. The two layers are interconnected by delicate bands called mesotendons, which carry the fine blood vessels to the tendons. Sheaths are found surrounding both flexor and extensor tendons at the wrist.

**SYNOVIAL SHEATHS OF FLEXOR TENDONS.** As the flexor tendons pass deep to the flexor retinaculum, they are enclosed in two synovial sheaths (Fig. 6-57). The larger one contains all the tendons of the flexor digitorum superficialis and flexor digitorum profundus, and is called the **common flexor tendon sheath** (formerly called the ulnar bursa). The smaller one, found on the radial side, is called the **tendon sheath of the flexor pollicis longus** (radial bursa), and contains the tendon of the long flexor of the thumb. The two sheaths extend into the forearm for about 2.5 cm proximal to the flexor retinaculum. The tendon sheath for the flexor pollicis longus extends distally to the terminal phalanx of the thumb, where the muscle inserts. The common flexor tendon sheath is continuous distally beyond the middle of the palm as the digital sheath only for the little finger. It is greatly reduced in diameter at the mid-palmar region by the formation of terminal diverticula about the tendons coursing to the second, third, and fourth digits. The tendons to these three fingers are without synovial sheaths for a short distance in the middle of the palm, but they have independent **digital sheaths**, beginning proximally over the heads of their metacarpal bones and continuing distally to the terminal phalanges, where the tendons of the flexor profundus insert.

**DIGITAL TENDON SHEATHS.** The tendons of the flexors digitorum superficialis and profundus are held in position along the digits by strong **fibrous sheaths**. These tunnels or canals are formed by the palmar surfaces of the phalanges and by strong collagenous bands that arch over the tendons and are attached to the margins of the phalanges on both sides. Opposite the middle of the proximal and second phalanges, the fibrous sheaths are reinforced by strong transversely coursing fibers, which form the **annular part** of the fibrous sheath. Opposite the joints, the fibrous sheaths are much thinner, and consist of obliquely coursing fibers. These form the **cruciate part** of the fibrous sheath (Fig. 6-57). At their proximal ends, the digital sheaths merge with the deeper parts

of the palmar aponeurosis. Within each of the five fibrous digital sheaths, there is a **synovial tendon sheath**. The fibrous sheath for the thumb is continuous with the tendon sheath of the flexor pollicis longus (radial bursa), and that for the little finger with the common flexor tendon sheath (ulnar bursa). Those for the other three fingers are closed proximally at the metacarpophalangeal joints (Fig. 6-57).

**SYNOVIAL SHEATHS OF EXTENSOR TENDONS.** Between the extensor retinaculum and the carpal bones, six tunnels are formed for the passage of tendons, each tunnel having a separate synovial sheath (Fig. 6-58). One is found in each of the following positions: (1) on the lateral (radial) side of the styloid process of the radius, for the tendons of the abductor pollicis longus and extensor pollicis brevis; (2) dorsal to the styloid process, for the tendons of the extensors carpi radialis longus and brevis; (3) about the middle of the dorsal surface of the radius, for the tendon of the extensor pollicis longus; (4) more medially, for the tendons of the extensor digitorum and extensor indicis; (5) opposite the interval between the radius and ulna, for the extensor digiti minimi; (6) between the head and styloid process of the ulna, for the tendon of the extensor carpi ulnaris. The sheaths lining these tunnels all begin proximal to the extensor retinaculum. Those for the tendons of the abductor pollicis longus, extensor pollicis brevis, extensors carpi radialis longus and brevis, and extensor carpi ulnaris stop immediately proximal to the bases of the metacarpal bones, while the sheaths for the extensor digitorum, extensor indicis, and extensor digiti minimi are prolonged an additional centimeter or more along the dorsum of the metacarpal bones.

### *Deep Fascia of the Hand*

**DEEP FASCIA OF THE PALM.** The investing layer of deep fascia in the palm is continuous with the antebrachial fascia on the volar aspect of the wrist. At the borders of the hand, the deep palmar fascia is continuous with the fascia of the dorsum, attaching to the fifth metacarpal bone medially, and the first and second metacarpal bones laterally, as it passes over them. The thenar fascia, which covers the muscular eminence at the radial side of the hand, and the hypothenar fascia, which covers the eminence of the

**Fig. 6-58.** The synovial sheaths and tendons on the dorsal aspect of the wrist and hand.

ulnar side, are similar in texture to the antebrachial fascia. The central part of the palm, however, is greatly strengthened into what is called the palmar aponeurosis.

The **palmar aponeurosis** (Fig. 6-59) is made up of two components: (1) a thick superficial stratum of longitudinal bundles, which are the direct continuation of the tendon of the palmaris longus, and (2) a thinner deep stratum of transverse fibers, which is continuous with the flexor retinaculum. The two strata are intimately fused and partly interwoven. The deeper portion is securely attached to the flexor retinaculum, which may contribute obliquely running fibers to the aponeurosis. The longitudinal bundles of

the superficial stratum form a uniform layer in the proximal part of the palm, but distally they fan out into divergent bands, which extend toward the bases of the digits and cover the long flexor tendons. The four bands to the fingers are heavier and more constant than the one to the thumb. Each of these bands has a double termination, superficially attaching to the skin and, more deeply, ending on the fibrous flexor tendon sheath. The most superficial fibers attach to the skin at the curved distal crease of the palm, while other superficial fibers terminate at the transverse crease at the base of the digits. The deeper portion of each band contributes to the fibrous tendon sheath in

**FIG. 6-59.** Superficial dissection of the palmar surface of the hand, demonstrating the palmar aponeurosis.

two ways: some of the fibers continue distally into the digit, assisting in the formation of the digital sheath, but the greater number of fibers form two arching ligamentous bands, which penetrate deeply toward the metacarpal bone on each side of the tendon. These bands attach to the bones, thus completing the formation of tunnels at the heads of the metacarpal bones. In the central part of the palm, as the longitudinal bands diverge, the intervals between them are occupied by the deeper transverse fibers. These **transverse fasciculi** extend as far distally as the heads of the metacarpal bones (Fig. 6-59).

From this site to the webs between the digits, the intervals are not covered by aponeurosis. In this distal, uncovered portion, therefore, the digital vessels and nerves, as well as the tendons of the lumbrical muscles, are more readily accessible to the surgeon. The intervals are closed distally by other transverse fibers, which occupy and support the webs between the digits. These more distal transverse fibers collectively constitute the **superficial transverse metacarpal ligament** (also called *superficial transverse ligament of the fingers*, *interdigital ligament*, *natatory ligament*). They are usually distinct from the

transverse fasciculi, which form the deep stratum of the palmar aponeurosis, and they attach to the digital sheaths at the bases of the proximal phalanges, merging into fibrous septa at the sides of the fingers. The digital vessels and nerves enter the fingers deep to the superficial transverse metacarpal ligament (Fig. 6-59).

As mentioned above, the band of longitudinal fibers that extends from the palmar aponeurosis toward the thumb is not as robust as the other four. Some of these longitudinal fibers attach to the longitudinal crease of the palm medial to the thumb, many fuse with the fascia of the thenar eminence, and a few assist in the formation of the sheath for the flexor pollicis longus tendon. When the palmaris longus is absent (about 13%), the attachment of the palmar aponeurosis to the flexor retinaculum is strengthened in order to compensate for the loss of continuity with the palmaris longus tendon. The palmaris brevis is a small but constant muscle that lies superficial to the hypothenar fascia. It has its origin at the ulnar border of the palmar aponeurosis and inserts into the skin at the ulnar border of the palm. The palmar aponeurosis is fused at its radial border with the fascia covering the thenar eminence. From this line of union, a fascial layer is continued deep into the palm and is attached to the first metacarpal bone, forming the **thenar septum**. Similarly, the aponeurosis is fused with the hypothenar fascia, and from this union a septum is continued deep to the fifth metacarpal to form the **hypothenar septum**. These two septa divide the palm into three compartments: a **thenar**, a **hypothenar**, and a **central compartment** (Fig. 6-60).

#### DEEP FASCIA OF THE DORSUM OF THE HAND.

The investing layer of deep fascia on the dorsum of the hand is directly continuous with the antebrachial fascia, which is thickened at the wrist by the addition of annular collagenous bundles into the extensor retinaculum. On the ulnar side of the hand, the deep fascia of the dorsum is continuous with the hypothenar fascia beyond its attachment to the dorsum of the fifth metacarpal bone, and at the radial border of the hand, it is continuous with the thenar fascia dorsal to the first metacarpal bone on which the fascia attaches. The deep fascia on the dorsum forms the superficial boundary of a flat compartment, which contains the tendons of the extensors of the digits.

The deep fascia on the dorsum of the thumb, after being attached to the dorsum of the second metacarpal bone, continues laterally over the first dorsal interosseous muscle, in the web between the thumb and the index finger, and is attached to the ulnar border of the first metacarpal bone. After forming a compartment for the extensor tendons of the thumb, it attaches to the radial border of the first metacarpal, where it becomes continuous with the thenar fascia.

#### Compartments of the Hand

Due to the attachments of the palmar fascia, the palm of the hand may be considered to be divided into four compartments: the **thenar**, **hypothenar**, **central**, and **interosseous-adductor compartments**. On the dorsum of the hand is found the **dorsal tendon compartment**. These compartments are enclosed by fascial layers and contain muscles, bones, and other structures. Between the compartments (and fascial layers) are the **fascial spaces** or **clefts**. An appreciation of these compartments and spaces is still of significant clinical importance in an understanding of the spread of infections and abscesses of the hand.

**THENAR COMPARTMENT.** The thenar compartment accounts for the thenar eminence of the palm and contains the short muscles of the thumb with the exception of the two heads of the adductor pollicis (Fig. 6-60). The *inferomedial* boundary is formed by the investing layer of deep fascia and its inward continuation, the thenar septum, which lies between the adductor and the flexor brevis. The compartment is closed by the attachment of this fascia proximally to the carpal bones and the flexor retinaculum; *distally*, to the first phalanx at the insertion of the enclosed muscles; *dorsally*, along the subcutaneous border of the first metacarpal bone; and *ventrally*, along the adductor. In addition to the abductor brevis, the flexor brevis, and the opponens, other structures occupying this compartment include the first metacarpal bone, the superficial palmar branch of the radial artery, and a portion of the tendon of the flexor pollicis longus enclosed in its tendon sheath. Within the compartment, the muscles are enclosed in their individual fascial sheaths and, for the most part, are separated from each other by fascial clefts, but these clefts do not communicate with

each other nor with the major fascial spaces of the palm.

**HYPOTHENAR COMPARTMENT.** This compartment on the ulnar side of the hand forms the hypothenar eminence and contains the short muscles of the little finger (Fig. 6-60). It is enclosed by the hypothenar investing fascia and the hypothenar septum, which lies between the flexor digiti minimi and the third palmar interosseous muscles. The fascia forms a closed compartment by attaching along the fifth metacarpal bone on both the dorsal and palmar aspects of the muscles that it surrounds. Within the compartment are found the hypothenar muscles and branches of the ulnar nerve and artery.

**CENTRAL COMPARTMENT.** The central compartment is bounded medially and laterally by the thenar and hypothenar fascial septa; superficially, by the palmar aponeurosis; and deeply, by a fascial lamina, which covers the deep surface of the long flexor tendon mass and overlies the interossei and metacarpal bones (Fig. 6-60). The compartment contains the tendons of the flexor digitorum superficialis and flexor digitorum

profundus, the lumbrical muscles, the superficial palmar arch, the palmar branch of the median nerve, and the superficial branch of the ulnar nerve. The compartment is narrow proximally, but widens distally as the tendons diverge toward their fingers. Its fascial attachments close the compartment proximally, but the tendon sheaths within it extend back into the forearm, and its tissues merge distally with those of the webs and digits.

**INTEROSSEOUS-ADDUCTOR COMPARTMENT.** Dorsal to the central compartment and separating the compartments of the palm and the dorsum of the hand is a region that contains principally the interossei and the adductor pollicis muscles; accordingly, this region is called the interosseous-adductor compartment. The compartment is enclosed by two fascial layers that are continuous with each other around its medial and lateral borders. The lamina on the dorsal surface, called the **dorsal interosseous fascia**, covers and is adherent to the dorsal surfaces of the second to fifth metacarpal bones and the intervening dorsal interossei (Fig. 6-61). The palmar

**FIG. 6-60.** Cross section of the hand, outlining (in red) the boundaries of the thenar, central palmar, and hypothenar compartments. Deep to the thenar and central palmar compartments of the palm, observe the large adductor-interosseous compartment. (From Hollinshead, *Anatomy for Surgeons*, 2nd Ed., Harper & Row, 1969.)

surface is covered by the **palmar interosseous fascia** on the ulnar half and by the fascia anterior to the adductor on the radial half. The compartment is closed by the attachment of these membranes at the origins of the muscles proximally and at their insertions distally. It contains the second, third, fourth, and fifth metacarpal bones, all the interossei, the transverse and oblique heads of the adductor pollicis, the deep palmar arch, and the deep branch of the ulnar nerve. The adductor and the interossei have been placed in the same rather than in separate compartments because the entire muscle mass lies deep to the palmar compartments and is separated from them by the major fascial spaces of the palm. A fascial cleft may separate the two heads of the adductor from each other and from the first dorsal interosseous, and these clefts may communicate with the thenar cleft or with the tissue spaces of the web between the thumb and index finger.

**DORSAL TENDON COMPARTMENT.** On the dorsum of the hand, the deep fascia splits into two layers, enclosing the dorsal tendon compartment which contains the extensor tendons. The more dorsal of these layers, called the **supratendinous layer**, is in continuity proximally with the extensor retinaculum. The deeper layer, which is called the **infratendinous layer**, lies between the extensor tendons and the dorsal interosseous fascia. The dorsal tendon compartment is closed at the sides of the hand by the fusion of the two membranes into a single sheet where both are attached to the dorsum of the second and fifth metacarpal bones. It is closed distally by a fusion of the two layers at the webs between the fingers and their attachment to the joint capsules and tendinous expansions of the digits.

### *Fascial Spaces (Clefts) in the Hand*

Fascial spaces or clefts are planes of cleavage between fascial layers and should not be confused with fascial compartments, which are enclosures formed by fascial layers and contain muscles, bones, and other structures. Fascial spaces of less clinical importance may occur within compartments, but those of great clinical importance lie between the compartments.

The major fascial space of the palm lies

deep to the fascia covering the deep surface of the long flexor tendon mass and anterior to the fascia covering the adductor pollicis muscle medially, and the interosseous muscles laterally, that is, it lies between the central palmar compartment and the interosseus-adductor compartment. Delicate septa attach to the metacarpal bones distally and extend toward the wrist, more or less subdividing the space. An **intermediate palmar septum**, which is attached to the middle metacarpal bone, is more constant and better developed than the rest and is commonly described as subdividing the larger space into two parts, the **middle palmar space** and the **thenar space** (Kanavel, 1939).

**MIDDLE PALMAR SPACE.** The middle palmar space or cleft is triangular in shape and separates the deep surface of the long flexor tendons from the interossei in the central part of the palm (Fig. 6-61). It lies between the palmar interosseous fascia and the fascia covering the deep surface of the long flexor tendon mass. The cleft may be closed at the wrist by adhesion between the fascial layers at the flexor retinaculum, or it may be continued proximally, deep to the flexor tendons, and communicate with the deep fascial space of the forearm that lies between the tendons of the flexor muscles and the pronator quadratus (Parona's space<sup>1</sup>). It is closed, medially, by the attachment of the hypothenar septum to the fifth metacarpal bone, and laterally, from the thenar cleft by the transparent, fibrous intermediate palmar septum which is attached along the middle metacarpal bone. This septum, instead of attaching to the flexor tendon mass directly over the middle metacarpal, may take an oblique course toward the region of the second metacarpal, causing the middle palmar space to extend into the radial portion of the palm, thereby overlapping to some extent the thenar space. The membrane between the middle palmar and the thenar cleft may be incomplete proximally, allowing the two spaces to communicate. Closely associated with the middle palmar space and acting as diverticula, are the clefts, called the **lumbrical canals**, that surround the second, third, and fourth lumbrical muscles.

**THENAR SPACE.** The thenar space overlies the palmar surface of the adductor pollicis

<sup>1</sup>Francesco Parona (19th century): An Italian surgeon (Novara).

**FIG. 6-61.** Transverse section across the hand, showing (in black) the fascial spaces. (After Kanavel, 1939.)

(Fig. 6-61). It is bounded, *medially*, by the intermediate palmar septum, which is attached to the middle metacarpal bone and separates it from the middle palmar space. The thenar space is bounded *laterally* by the thenar septum and the first metacarpal bone; *proximally*, by the flexor retinaculum; and *distally*, by the extent of the transverse head of the adductor pollicis muscle. The thenar space is commonly continuous with the cleft between the two heads of the adductor pollicis, and between the adductor and the first dorsal interosseous. It may communicate with the middle palmar space proximally, and it usually has a diverticulum, the lumbrical canal, extending along the first lumbrical muscle.

**LUMBRICAL CANALS.** This is a term used to designate the fascial clefts that separate the lumbrical muscles from the denser connective tissue that surrounds them. These canals are distal extensions or diverticula of the fascial spaces of the palm. The canal associated with the first lumbrical muscle (index finger) projects from the thenar space, while the lumbrical canals of the second, third, and fourth muscles extend distally from the middle palmar space.

**DORSAL SUBCUTANEOUS SPACE.** On the *dorsum* of the hand, the dorsal subcutaneous space separates the superficial fascia from the deep fascia (Fig. 6-61). It extends *distally* into the fingers and *proximally* into the forearm. It is closed at the radial and ulnar borders of the hand by the attachment of the superficial fascia to the deep fascia of the

palm. Although of less clinical importance than the palmar spaces, it allows pus to spread quite easily over the entire *dorsum*, if an infection is present.

**DORSAL SUBAPONEUROTIC SPACE.** Deep to the investing fascia, and between it and the dorsal interosseous fascia, lies the dorsal subaponeurotic space (Fig. 6-61). It is closed at the sides of the hand by the fusion of the two fascial layers near their attachment to the second and fifth metacarpal bones. It is closed distally by the fusion of the two layers and their union with the joint capsules and extensor expansions of the digits. Proximally, it is limited by the attachment of the tendon sheaths to the bones and ligaments of the wrist. This space does not communicate with the dorsal subcutaneous space, nor with the palmar spaces, and it does not pass from the hand into the forearm.

**Clinical Considerations.** The relationship of the fascial spaces to each other and to the tendon sheaths may be discussed by reviewing the probable spread of an infection, independent of the participation of blood vessels or lymphatics.

A *subcutaneous abscess on the dorsum* of the hand or in the webs of the fingers is generally directed toward the surface locally because of the softness of the tissues. A *subcutaneous abscess in the palm* might reach the surface or spread to the webs, but would not be likely to penetrate the palmar aponeurosis. An *abscess of the index finger*, after penetrating to the deeper tissues, might progress proximally until it arrived in the lumbrical canal of that finger and, through this path, reach the thenar space. *Abscesses of the middle, ring, or little fingers*

might reach the palmar space by a similar path. Infections that have reached either of the deep palmar spaces may spread to the other space by penetrating the intermediate palmar septum, or they may ascend to the deep fascial space (of Parona) above the wrist.

*Infections of the flexor tendons* of the little finger or thumb for a period of time are confined to the common flexor tendon sheath or to the tendon sheath of the flexor pollicis longus. The infection then ascends and ruptures into the deep fascial space of the forearm. An infection in the digital tendon sheath of the index finger can be expected to rupture into the thenar space; if it is in the middle or fourth finger, it will rupture into the middle palmar space.

An infection in the subaponeurotic space can be expected to spread throughout the space and then eventually rupture into the webs of the fingers or at the sides of the hand.

## MUSCLES OF THE HAND

The muscles of the hand are subdivided into three groups: (1) those of the thumb, which occupy the radial side and produce the **thenar eminence**; (2) those of the little finger, which occupy the ulnar side and give rise to the **hypothelar eminence**; (3) those in the middle of the palm, and the interosseous muscles between the metacarpal bones.

### Thenar Muscles

The thenar muscles are the intrinsic muscles of the thumb. They include:

- Abductor pollicis brevis
- Opponens pollicis
- Flexor pollicis brevis
- Adductor pollicis
  - Oblique head
  - Transverse head

**ABDUCTOR POLLICIS BREVIS.** The abductor pollicis brevis is a thin, flat muscle, placed most superficially on the radial side of the thenar eminence (Figs. 6-62; 6-64). It arises from the flexor retinaculum, the tuberosity of the scaphoid, and the ridge of the trapezium, frequently by two distinct slips. Coursing laterally and distally, it is inserted by a thin, flat tendon into the radial side of the base of the proximal phalanx of the thumb and the capsule of the metacarpophalangeal articulation.

The abductor pollicis brevis is sometimes divided into outer and inner parts, and accessory slips to the muscle may come from

the abductor pollicis longus tendon or the palmaris longus. More rarely, slips to the muscle may come from the extensor carpi radialis longus, the styloid process of the radius, the opponens pollicis, or the fascia over the thenar muscles.

**Action.** The **abductor pollicis brevis** abducts the thumb at the carpometacarpal and metacarpophalangeal joint by drawing it away in a plane at right angles to that of the palm of the hand.

**Nerve.** The abductor pollicis brevis is supplied by a branch of the **median nerve**, containing fibers from the eighth cervical and first thoracic nerves.

**OPPONENS POLLICIS.** The opponens pollicis is a small triangular muscle placed beneath the abductor pollicis brevis (Figs. 6-62 to 6-64). It arises from the ridge on the trapezium and from the flexor retinaculum, passes distally and laterally, and is inserted into the whole length of the metacarpal bone of the thumb on its radial side.

**Action.** The **opponens pollicis** abducts, flexes, and medially rotates the first metacarpal bone, bringing the thumb across the palm from lateral to medial. This action, called **opposition**, occurs primarily at the carpometacarpal joint and allows the pad of the thumb to come into contact with the pads of the other fingers.

**Nerve.** The opponens pollicis is innervated by a branch of the **median nerve**, containing fibers from the eighth cervical and first thoracic nerves.

**FLEXOR POLLICIS BREVIS.** The flexor pollicis brevis lies medial and distal to the abductor pollicis brevis (Figs. 6-62; 6-64) and consists of superficial and deep parts. The **superficial part** is more lateral and larger than the deep part and arises from the distal border of the flexor retinaculum and the distal part of the tubercle on the trapezium. It passes along the radial side of the tendon of the flexor pollicis longus and, becoming tendinous, is inserted into the radial side of the base of the proximal phalanx of the thumb. In its tendon of insertion is found the radial sesamoid bone of this joint. The **deep part** is considerably smaller and located medial to the superficial part. It arises from the trapezoid and capitate bones, and its fibers take an oblique course to join the fibers of the superficial part, inserting by a common tendon onto the radial side of the proximal phalanx of the thumb.

There has been some disagreement with regard to the identity of the deep head of this

**Fig. 6-62.** Muscles of the right palm. The long tendons have been cut as they pass over the metacarpophalangeal joints. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban and Schwarzenberg, Munich, 1980).

muscle, but the study of Day and Napier (1961) showed that nearly 80% of the hands that they examined followed the foregoing description. The deep head may be absent.

**Action.** The **flexor pollicis brevis** flexes the proximal phalanx at the metacarpophalangeal joint and then, indirectly, medially rotates the metacarpal bone of the thumb at the carpometacarpal joint.

**Nerve.** The superficial part of the flexor pollicis brevis is supplied by a branch of the **median nerve**, containing fibers from the eighth cervical and first thoracic nerves. The deep part usually receives innervation from the deep branch of the **ulnar nerve**, which also contains fibers from the eighth cervical and first thoracic nerves.

**ADDUCTOR POLLICIS.** The adductor pollicis consists of oblique and transverse heads. The **oblique head** (Figs. 6-62; 6-63) arises by

several slips from the capitate bone, the bases of the second and third metacarpals, the intercarpal ligaments, and the sheath of the tendon of the flexor carpi radialis. It may also receive a slip from the flexor retinaculum. From its origin most of the fibers pass obliquely downward and converge in a tendon that contains a sesamoid bone and is inserted into the ulnar side of the base of the proximal phalanx of the thumb. Some fibers usually pass more obliquely beneath the tendon of the flexor pollicis longus to join the lateral portion of the flexor pollicis brevis and the abductor pollicis brevis.

The **transverse head** of the adductor pollicis is the most deeply situated of the thenar muscles (Figs. 6-62 to 6-64). It is triangular in shape and arises by a broad base from the distal two-thirds of the palmar sur-

**Fig. 6-63.** A dissection of the palm of the right hand, showing the two parts of the adductor pollicis muscle, as well as the opponens pollicis and opponens digiti minimi muscles.

face of the third metacarpal bone. Its converging fibers form a distal border that is nearly transverse. Coursing toward the thumb, they join the fibers of the oblique head to be inserted onto the ulnar side of the base of the proximal phalanx of the thumb.

**Action.** The **adductor pollicis** brings the abducted proximal phalanx toward the palm of the hand, thereby adducting the thumb.

**Nerve.** The adductor pollicis is supplied by the deep palmar branch of the **ulnar nerve**, containing fibers from the eighth cervical and first thoracic nerves.

### Hypothenar Muscles

The hypothenar muscles are the intrinsic muscles of the little finger. They are the:

Palmaris brevis  
Abductor digiti minimi  
Flexor digiti minimi brevis  
Opponens digiti minimi

**PALMARIS BREVIS.** The palmaris brevis is a thin, quadrilateral superficial muscle, placed beneath the integument of the ulnar side of the hand (Fig. 6-59). It arises by tendinous fasciculi from the flexor retinaculum and

palmar aponeurosis, and it inserts into the skin on the ulnar border of the palm of the hand.

**Action.** The **palmaris brevis** draws the skin at the ulnar side of the palm toward the middle of the palm, increasing the height of the hypothenar eminence, as in clenching the fist. It also holds the hypothenar subcutaneous pad in place, as in catching a ball.

**Nerve.** The palmaris brevis is supplied by the superficial branch of the **ulnar nerve**, containing fibers from the eighth cervical and first thoracic nerves.

**ABDUCTOR DIGITI MINIMI.** This abductor of the little finger is situated on the ulnar border of the palm of the hand (Figs. 6-62 and 6-64). It arises from the pisiform bone and from the tendon of the flexor carpi ulnaris; it ends in a flat tendon, which divides into two slips: one is inserted into the ulnar side of the base of the first phalanx of the little finger; the other is inserted into the ulnar border of the dorsal digital aponeurosis of the extensor digiti minimi.

Accessory slips may join the muscle from the tendon of the flexor carpi ulnaris, the flexor retinaculum, the fascia of the distal

FIG. 6-64. The muscles of the left hand. Palmar surface.

forearm, or the tendon of the palmaris longus. A part of the muscle may insert into the fifth metacarpal bone.

**Action.** The *abductor digiti minimi* abducts the little finger away from the ring finger, and it also flexes the proximal phalanx at the metacarpophalangeal joint.

**Nerve.** The *abductor digiti minimi* is innervated

by the deep branch of the **ulnar nerve**, containing fibers from the eighth cervical and first thoracic nerves.

**FLEXOR DIGITI MINIMI BREVIS.** This short flexor of the little finger lies on the same plane as the preceding muscle, on its radial side (Figs. 6-62; 6-64). It arises from the convex surface of the hamulus of the hamate

bone and the palmar surface of the flexor retinaculum, and it is inserted into the ulnar side of the base of the proximal phalanx of the little finger. It is separated from the abductor, at its origin, by the deep branches of the ulnar artery and nerve. This muscle is sometimes wanting, in which case the abductor is unusually large.

**Action.** The *flexor digiti minimi brevis* flexes the little finger at the metacarpophalangeal joint.

**Nerve.** The *flexor digiti minimi brevis* is supplied by the deep branch of the **ulnar nerve**, containing fibers from the eighth cervical and first thoracic nerves.

**OPPONENS DIGITI MINIMI.** The *opponens digiti minimi* is triangular in shape and placed immediately beneath the abductor and flexor (Figs. 6-62; 6-63). It arises from the convexity of the hamulus of the hamate bone and contiguous portion of the flexor retinaculum. It is inserted onto the whole length of the metacarpal bone of the little finger, along its ulnar margin.

**Action.** The *opponens digiti minimi* abducts, flexes, and laterally rotates the fifth metacarpal, thereby bringing the little finger in opposition to the thumb.

**Nerve.** The *opponens digiti minimi* is supplied by the deep branch of the **ulnar nerve**, containing fibers from the eighth cervical and first thoracic nerves.

### Intermediate Muscles

Lumbricals  
Interossei

**THE LUMBRICALS.** The lumbrical muscles (Fig. 6-64) are four small fleshy fasciculi that are associated with the tendons of the flexor digitorum profundus. The first and second arise from the radial sides and palmar surfaces of the tendons of the index and middle fingers, respectively; the third lumbrical arises from the contiguous sides of the tendons of the middle and ring fingers; and the fourth lumbrical arises from the contiguous sides of the tendons of the ring and little fingers. Each passes to the radial side of the corresponding finger, and opposite the metacarpophalangeal joint is inserted into the tendinous expansion of the extensor digitorum, which is called the extensor hood and covers the dorsal aspect of the finger.

**Action.** Each lumbrical muscle flexes the proximal phalanx at the corresponding metacarpophalangeal joint and extends the two distal phalanges at the interphalangeal joints.

**Nerves.** The first and second lumbrical muscles are supplied by twigs from the third and fourth digital branches of the **median nerve**, containing fibers from the eighth cervical and first thoracic nerves. The third and fourth lumbricals receive twigs from the deep palmar branch of the **ulnar nerve**, which also contains fibers from the eighth cervical and first thoracic segments. The third lumbrical may receive filaments from both nerves, or even all its supply from the median nerve.

**Variations.** The lumbricals may vary in number from two to five or six, and there is considerable variation in their attachments.

### THE INTEROSSEI

The interossei are so named because they occupy the intervals between the metacarpal bones. They are divided into two sets, dorsal and palmar.

**DORSAL INTEROSSEI.** Each of the four dorsal interossei (Figs. 6-62; 6-65) is a bipennate muscle that arises by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle attaches distally. Each interosseous muscle is inserted into the base of the proximal phalanx and into the corresponding aponeurosis that forms the dorsal hood of the tendon of the extensor digitorum. Between the double origin of each of these muscles is a narrow triangular interval. Through the first of these intervals the radial artery passes, and through each of the other three a perforating branch from the deep palmar arch is transmitted.

The **first dorsal interosseous** (also called the **abductor indicis**) is larger than the others. It is flat and triangular in form, and its two heads of origin are separated by a fibrous arch for the passage of the radial artery from the dorsum to the palm of the hand. The **lateral head** arises from the proximal half of the ulnar border of the first metacarpal bone, while the **medial head** arises from almost the entire length of the radial border of the second metacarpal bone. Its tendon is inserted almost entirely onto the radial side of the proximal phalanx of the index finger, although some fibers may reach the dorsal extensor aponeurosis.

**Fig. 6-65.** The dorsal interossei of left hand. Line down middle finger represents an imaginary axis. Abduction and adduction are determined according to this reference.

The **second** and **third dorsal interosseous** muscles both insert onto the middle finger, the former to its radial side and the latter to its ulnar side. The tendon of the second muscle inserts about equally onto the proximal phalanx and the dorsal extensor aponeurosis, while most of the tendon of the third muscle attaches to the dorsal extensor aponeurosis.

The tendon of the **fourth dorsal interosseous** muscle inserts onto the ulnar side of the ring finger. Its fibers are attached about equally to the proximal phalanx and the dorsal extensor aponeurosis.

**Action.** The **dorsal interossei** abduct the fingers from an imaginary line drawn longitudinally through the axis of the middle finger (Fig. 6-65). They also flex the fingers at the metacarpophalangeal joints and extend the two distal phalanges at the interphalangeal joints.

**Nerves.** All the dorsal interossei are supplied by the deep palmar branch of the **ulnar nerve**, containing fibers from the eighth cervical and first thoracic nerves.

**PALMAR INTEROSSEI.** The palmar interossei are smaller than the dorsal interossei,

and they are placed upon the palmar surfaces of the metacarpal bones rather than between them. Three palmar interossei are clearly distinct, but some authors describe four muscles. Each arises from the entire length of the metacarpal bone of one finger and is inserted into the side of the base of the proximal phalanx and aponeurotic expansion of the extensor digitorum tendon to the same finger.

The **first** arises from the ulnar side of the second metacarpal bone and is inserted into the same side of the proximal phalanx of the index finger. The **second** arises from the radial side of the fourth metacarpal bone and is inserted into the same side of the ring finger. The **third** arises from the radial side of the fifth metacarpal bone and is inserted into the same side of the little finger.

Some authors add another palmar interosseous muscle to their description, attaching the term *first palmar interosseous* to a few fibers that pass from the base of the first metacarpal to the base of the proximal phalanx. In their descriptions, the other muscles in the foregoing discussion become the second, third, and fourth muscles, respectively. Since the thumb has a large adductor muscle of its own, these fibers have been considered as part of that muscle in the present account.

**Fig. 6-66.** The palmar interossei of left hand.

**Action.** The palmar interossei adduct the fingers toward an imaginary longitudinal line through the axis of the middle finger (Fig. 6-66). They also flex the proximal phalanx at the metacarpophalangeal joint and extend the two distal phalanges at the interphalangeal joints.

**Nerves.** The palmar interossei are supplied by twigs from the deep palmar branch of the ulnar nerve, containing fibers from the eighth cervical and first thoracic nerves.

**Group Actions.** *Flexion of the fingers* in grasping an object is performed by the flexors digitorum superficialis and profundus. The wrist extensors contract synergistically to prevent flexion of the wrist while the fingers are being flexed. The action of both flexors on the two terminal phalanges can be performed independent of flexing the proximal phalanx by calling into play the synergistic action of the extensor digitorum on the proximal phalanx. Flexion of the proximal phalanx at the same time as extension of the two distal joints is performed by the dorsal and palmar interossei and the lumbrical muscles.

*Extension of the fingers* is performed by the extensor digitorum, extensor indicis, and extensor digiti minimi. The wrist flexors contract synergistically to prevent extension at the wrist while the fingers are being extended. The long extensors have a relatively weak action on the two terminal joints and are assisted in this action by the lumbricals and the interossei.

*Abduction of the fingers* is performed by the dorsal interossei and the abductor digiti minimi, considering the longitudinal axis of the middle finger as the center of the hand. Full abduction can be carried out only if the fingers are extended.

*Adduction of the fingers* is performed by the palmar interossei, and this action can be carried out with the fingers either flexed or extended.

The thumb is so placed that its plane of flexion and extension is at right angles to that of the fingers. Flexion and extension of the thumb, therefore, are in the same plane as abduction and adduction of the fingers; abduction and adduction of the thumb are in the same plane as flexion and extension of the fingers.

*Flexion of the distal phalanx of the thumb* is performed by the flexor pollicis longus, and flexion of the proximal phalanx alone by the flexor pollicis brevis. *Extension of the distal phalanx* is performed by the extensor pollicis longus, the proximal phalanx by the extensor pollicis brevis. *Abduction of the thumb* is by the abductors pollicis longus and brevis; adduction by the adductor pollicis. It is seldom that extension or abduction is performed independently of each other, most normal activity being a mixture of the two movements. When the thumb is used in grasping, it is initially abducted by the abductors and rotated by the opponens so that its palmar surface faces the palm of the hand. The actual grasping then is performed largely by the flexor pollicis longus.

## Fasciae and Muscles of the Lower Limb

The fasciae and muscles of the lower limb will be subdivided into groups corresponding to the different regions of the limb.

Muscles of the iliac region  
Muscles of the thigh  
Muscles of the leg  
Muscles of the foot

### MUSCLES AND FASCIAE OF THE ILIAC REGION

Psoas major  
Psoas minor  
Iliacus

The fascia covering the intra-abdominal surface of the iliacus and psoas muscles is part of the endoabdominal or internal investing layer of deep fascia; it forms a continuation over these muscles of the transversalis fascia that lines the abdominal cavity. Following the iliac muscles under the inguinal ligament and into the thigh, it becomes continuous with the fascia lata, which is a portion of the external investing fascia.

**ILIAC FASCIA.** The posterior abdominal portion of the iliac fascia is attached superiorly to the entire length of the inner lip of the crest of the ilium, along with the muscle. Above the iliac crest it is continuous with the definitive transversalis fascia, and near the vertebral column, it is continuous with the fascia covering the abdominal surface of the quadratus lumborum muscle. It is continuous medially with the psoas fascia, and after attaching to the arcuate line of the ilium, it continues down into the lesser pelvis as the obturator internus fascia. At the inguinal ligament it fuses with the transversalis fascia of the lateral portion of the anterior abdominal wall, and follows the surface of the iliacus under the ligament and into the thigh. It is securely attached to the ligament as it passes beneath it, and in the thigh, it becomes continuous with the part of the fascia lata overlying the sartorius muscle laterally and with the iliopectineal fascia medially.

**PSOAS FASCIA.** The superior extremity of the psoas fascia is intimately blended with

the medial arcuate ligament of the diaphragm, which stretches from the bodies to the transverse processes of the first or second lumbar vertebrae. It is attached medially, by a series of arched processes, to the intervertebral discs and prominent margins of the vertebrae and to the upper part of the sacrum. The intervals left between these arched processes and the constricted bodies of the vertebrae transmit the lumbar arteries and veins and the filaments of the sympathetic trunk. It is continuous laterally with the fasciae covering the quadratus lumborum and iliacus muscles. At the inguinal ligament and in the thigh, the psoas and iliac fasciae help to form part of the iliopectineal fascia.

**ILIOPECTINEAL FASCIA.** The iliopectineal fascia is formed by a blending of: (1) the fascia covering the femoral portions of the iliacus and psoas; (2) the fascia over the proximal portion of the pectineus; and (3) a thickened band, called the **iliopectineal arch**, which dips between the psoas major and the femoral vessels as they pass under the inguinal ligament. Thus, the iliopectineal fascia is continuous, under the inguinal ligament, with the iliac, the psoas, and the transversalis fasciae. The fascial layer covering the iliacus, psoas major, and pectineus muscles forms a fascial sheet that stretches across the floor of the femoral (Scarpa's) triangle. At the junction of the iliopsoas and pectineal portions of the iliopectineal fascia, it attaches firmly to the iliopectineal eminence of the ilium and to the pubocapsular ligament of the hip joint. From the attachment to the iliopectineal eminence, the fascia passes outward as the thickened band mentioned above, the iliopectineal arch, which separates the psoas major muscle and the femoral vessels and courses toward the inguinal ligament to which it becomes attached. This band divides the interval deep to the inguinal ligament, that is, between the ligament and the pelvic bone, into two parts known as the lacuna musculorum and the lacuna vasorum. The **lacuna musculorum** contains the iliacus and psoas major muscles and the femoral nerve. The **lacuna vasorum** contains the femoral artery and vein and the femoral canal.

The **iliopsoas** muscle is frequently regarded as a single structure because it is a blending of two muscles, the psoas major and the iliacus. Its two parts, however, will be described separately.

**PSOAS MAJOR.** The psoas major is a long fusiform muscle lateral to the lumbar region of the vertebral column and brim of the lesser pelvis (Fig. 6-67). It arises (1) from the anterior surfaces and lower borders of the transverse processes of all the lumbar vertebrae; (2) by five slips from the sides of the bodies and the corresponding intervertebral discs of the last thoracic and all the lumbar vertebrae (each slip is attached to the adjacent upper and lower margins of two vertebrae, and to the intervertebral disc); (3) from a series of tendinous arches that extends across the constricted parts of the bodies of the lumbar vertebrae between the previously described slips. The lumbar arteries and veins and filaments from the sympathetic trunk pass beneath these tendinous arches. The muscle proceeds downward across the brim of the lesser pelvis and, diminishing gradually in size, passes beneath the inguinal ligament, anterior to the capsule of the hip joint. It ends in a tendon that also receives nearly all of the fibers of the iliacus and is inserted onto the lesser trochanter of the femur. The large **subtendinous iliac bursa**, which may communicate with the cavity of the hip joint, separates the tendon from the pubis and the capsule of the joint (Fig. 6-70).

**Action.** The **psoas major** (in conjunction with the iliacus) is a powerful flexor of the thigh at the hip joint. If both psoas major muscles are fixed from below, they act as important flexors of the trunk on the hip, as in sitting up from the supine position. The psoas major may assist in maintaining posture by preventing hyperextension at the hip joint. Although mechanically it appears to be a medial rotator of the thigh, electromyographic studies contradict this interpretation and, in fact, indicate that it may be active in lateral rotation.

**Nerves.** The psoas major is innervated by branches of the lumbar plexus, containing fibers from the **second, third, and fourth lumbar nerves**.

**PSOAS MINOR.** The psoas minor is a long, slender muscle that is placed anterior to the psoas major on the posterior abdominal wall (Fig. 6-67). It arises from the sides of the bodies of the twelfth thoracic and first lumbar vertebrae and from the intervertebral disc between them. It ends in a long, flat tendon which is inserted into the pectineal line, the iliopectineal eminence, and, laterally, the iliac fascia. This muscle is absent bilaterally in over half the subjects studied.

**Fig. 6-67.** Muscles of the iliac and anterior femoral regions.

**Action.** The **psoas minor** is a weak flexor of the trunk and lumbar spinal column.

**Nerve.** The **psoas minor** is supplied by a branch of the **first lumbar nerve**.

**THE ILIACUS.** The **iliacus** is a flat, triangular muscle that fills the iliac fossa (Fig. 6-67). It arises from the superior two-thirds of this fossa and from the inner lip of the iliac crest; dorsally from the anterior sacroiliac and the iliolumbar ligaments and base of the sacrum; and anteriorly from as far as the anterior superior and anterior inferior iliac spines, and the notch between them. Most of the fibers converge inferiorly to be inserted into the lateral aspect of the tendon of the **psoas major**, but some fibers extend to the body of the femur for about 2.5 cm distal and anterior to the lesser trochanter.

**Action.** The **iliacus** (along with the **psoas major**) is a powerful flexor of the thigh at the hip joint. It joins the **psoas** in a number of other actions as the **iliopsoas**.

**Nerves.** The **iliacus** is supplied by branches of the **femoral nerve**, containing fibers from the second and third lumbar nerves.

**Variations.** The **iliacus minor** or **iliocapsularis**, a small detached part of the **iliacus**, is frequently present. It arises from the anterior inferior spine of the ilium and is inserted into the lower part of the intertrochanteric line of the femur or into the iliofemoral ligament.

## FASCIAE AND MUSCLES OF THE THIGH

The fascial layers of the thigh and buttocks overlie four functional groups of muscles which will be described as follows:

- Anterior femoral muscles
- Medial femoral muscles
- Muscles of the gluteal region
- Posterior femoral muscles

The fascial layers include the superficial fascia and the fascia lata; the latter represents the deep fascia, which continues over the gluteal region as the gluteal fascia.

**SUPERFICIAL FASCIA.** The superficial fascia forms a prominent layer over the entire thigh. It usually contains a considerable amount of fat, but it varies in thickness in different regions. It is continuous with the superficial fascia of the abdomen, that of the leg, and, above the gluteal region, with the superficial fascia of the back. It may be sepa-

rated into a superficial fatty layer and a deeper membranous layer between which are found the superficial vessels and nerves, the superficial inguinal lymph nodes, and the great saphenous vein. In well-nourished individuals, the fatty tissue of the superficial layer is usually divided by fibrous membranes into two or three subsidiary layers, which are associated with the emergence of the superficial nerves. The deep or fibrous layer is adherent to the fascia lata a little below the inguinal ligament and along the upper medial portion of the thigh. It is attached to the margin of the **saphenous hiatus** (fossa ovalis) and fills the opening itself with an irregular layer of spongy tissue, which is called the **cribriform fascia** because it is pierced by numerous openings for the passage of the great saphenous vein and other blood and lymphatic vessels.

A large subcutaneous bursa is found in the superficial fascia over the patella.

**FASCIA LATA.** The external investing or deep fascia of the thigh is named the fascia lata from its broad extent. Its thick, lateral portion is commonly taken to be typical of its texture, but it is thin in some areas where it has not been reinforced by fibrous contributions from the tendons. *Superiorly*, it is on the same plane as the external oblique aponeurosis and thoracolumbar fasciae after being attached to the pelvis and inguinal ligament; *distally*, it is continuous with the fascia of the leg.

The **medial portion** of the fascia lata overlies the adductor group of muscles. It is thin and gray, and it is not aponeurotic. It is attached to the ischial tuberosity and ischio-pubic ramus, and beyond this it is on the same plane as the deep fascia of the perineum. At the knee it is thick and aponeurotic, having been strengthened by fibers from the tendon of the sartorius muscle.

The **anterior portion** of the fascia lata is attached to the pubic tubercle, inguinal ligament, and anterior superior iliac spine. Just below the lateral half of the inguinal ligament, it is a single sheet formed by the fusion of three abdominal fasciae. Of these, the most superficial is the deep fascia overlying the aponeurosis of the external oblique (fascia innominata), which passes superficial to the inguinal ligament; the middle one is the transversalis fascia on the inner aspect of the anterior abdominal wall, which passes under the inguinal ligament; the internal one

also passes under the inguinal ligament and is the continuation of the iliac fascia. Below the medial half of the inguinal ligament, the middle and internal layers mentioned above fail to join the fascia lata at the ligament and continue into the thigh as the anterior and posterior portions of the femoral sheath. The fascia lata in this ventromedial region over the femoral vessels is thickened and laminated and has an opening through it called the saphenous hiatus for the passage of the great saphenous vein. The outer lamina is attached to the pubic tubercle along with the inguinal ligament. It has a free falciform margin which crosses the proximal end of the great saphenous vein and spirals distally around the vein to join the deep lamina medial to the vein. The two laminae are separated by a pad of fatty tissue. The anterior portion of the fascia lata is thicker than the medial, but is truly aponeurotic only near the knee, where it is reinforced by fibers from the tendons of the quadriceps femoris muscle.

The **lateral portion** of the fascia lata is a thick strong aponeurosis containing the tendinous fibers of insertion of the gluteus maximus and the tensor fasciae latae muscles. It is attached proximally to the crest of the ilium and the dorsum of the sacrum. Between the iliac crest and the superior border of the gluteus maximus, it is thickened by vertical tendinous bundles and is known as the **gluteal aponeurosis** (Fig. 6-72), which is used by the gluteus medius for part of its origin. At the border of the gluteus maximus, the gluteal aponeurosis splits to enclose the muscle. Thus, the thin external layer of this **gluteal fascia** is closely bound to the superficial fascia and the muscle, and it sends septa down between large bundles of the muscle. In the region over the greater trochanter, the muscular fasciculi end in a broad tendon, which becomes fused with the fascia lata and is called the **iliotibial tract**. Below the anterior part of the iliac crest, the fascia splits to enclose the tensor fasciae latae, which is inserted into the iliotibial tract below the gluteus maximus. The iliotibial tract is separated from the underlying vastus lateralis by a distinct fascial cleft. It is inserted into the tibia and is blended with fibrous expansions from the vastus lateralis and biceps femoris muscles.

The **posterior portion** of the fascia lata is formed proximally by the union of the two

layers of fascia enclosing the gluteus maximus at its inferior border. It descends to cover the hamstring muscles and the popliteal fossa.

Two strong intermuscular septa (Fig. 6-69) connect the deep surface of the fascia lata with the linea aspera of the femur. The **lateral intermuscular septum** is the stronger. It separates the vastus lateralis from the biceps femoris and is used by both muscles for the origin of some of their fibers. It extends from the insertion of the gluteus maximus to the lateral condyle. The **medial intermuscular septum** lies between the vastus medialis and the adductors and pectineus. Its superficial portion near the fascia lata splits to enclose the sartorius muscle, and in its descent the medial septum contributes to the formation of the adductor canal, which transmits the femoral vessels.

The **saphenous hiatus** is an oval aperture in the fascia lata in the proximal part of the

thigh, a little below the medial end of the inguinal ligament (Fig. 6-68). The great saphenous vein passes through the hiatus just before it joins the femoral vein. The fascia lata in this part of the thigh is laminated into two leaves separated by fat. The superficial layer is attached to the inguinal ligament and pubic tubercle. It ends abruptly in a free border, the **falciform margin of the fossa**, which forms a spiral rim beginning at the pubic tubercle and extending around the superior, lateral, and then inferior aspects of the saphenous vein. Medial to the vein, the superficial leaf merges with the deep leaf. The upper and lateral part of the falciform margin is called the **superior cornu**, while the medial and lower part is called the **inferior cornu**. The deep leaf is formed by the pectineal, iliopectineal, and iliac fasciae. The hiatus is filled and covered by a thickened pad derived from the deep layer of superficial fascia, called the **cribriform fascia**.

Fig. 6-68. The saphenous hiatus (fossa ovalis).

**Anterior Femoral Muscles**

Sartorius  
 Quadriceps femoris  
   Rectus femoris  
   Vastus lateralis  
   Vastus medialis  
   Vastus intermedius  
 Articularis genus

**THE SARTORIUS.** The sartorius is the longest muscle in the body (Figs. 6-67; 6-69). It is narrow and ribbon-like, and it arises by tendinous fibers from the anterior superior iliac spine and the upper half of the notch below it. The sartorius passes obliquely across the upper anterior part of the thigh from lateral

to medial, and it then descends vertically as far as the medial side of the knee, passing posterior to the medial condyle of the femur. It ends in a tendon that curves obliquely anteriorly and expands into a broad aponeurosis, which is inserted into the proximal part of the medial surface of the body of the tibia, anterior to the gracilis and semitendinosus, and nearly as far forward as the anterior crest. A bursa separates the insertion of the sartorius from that of the underlying gracilis. The proximal part of the aponeurosis is curved backward over the upper edge of the tendon of the gracilis so as to be inserted behind it. A tendinous expansion from the upper margin of its insertion blends with the capsule of the knee joint; another, from its

**FIG. 6-69.** Cross section through the middle of the thigh. (Eycleshymer and Schoemaker, 1911.)

lower border, blends with the fascia on the medial side of the leg.

**Action.** The *sartorius* flexes, abducts, and laterally rotates the thigh at the hip joint. It also flexes the leg at the knee joint and, after flexing, rotates it slightly medially. Its complicated actions are thought to draw the lower extremity into a sitting position, with the leg crossed in such a way that the heel of one limb is placed on the knee of the opposite limb, the so-called sitting tailor's position.

**Nerves.** The *sartorius* is supplied by branches of the **femoral nerve**, usually two in number, containing fibers from the second and third lumbar nerves. These generally arise from the femoral nerve with its anterior cutaneous branches.

**Variations.** At times slips of origin to the *sartorius* are derived from the outer end of the inguinal ligament, the notch of the ilium, the iliopectineal line, or the pubis. The muscle may be split into two parts, with one part being inserted into the fascia lata, the femur, the ligament of the patella, or the tendon of the *semitendinosus*.

**QUADRICEPS FEMORIS.** The quadriceps femoris consists of four component muscles or heads of origin on the anterior thigh. It is the great extensor muscle of the leg, forming a large fleshy mass that covers the front and sides of the femur. It is subdivided into separate portions, which have received distinctive names. One, occupying the middle of the thigh and connected above with the ilium, is called the **rectus femoris** because of its straight course (Fig. 6-67). The other three lie in immediate connection with the body of the femur, which they cover from the trochanters to the condyles. The portion on the lateral side of the femur is termed the **vastus lateralis**; that covering the medial side, the **vastus medialis**; and that between, the **vastus intermedius**.

The **rectus femoris** is situated in the middle of the anterior thigh (Fig. 6-67). It is fusiform in shape, and its superficial fibers are arranged in a bipennate manner, whereas its deep fibers course straight down to the deep aponeurosis. It arises by two tendons: one, the anterior or straight, attaches to the anterior inferior iliac spine; the other, the posterior or reflected, attaches to a groove above the posterior brim of the acetabulum. The two unite at an acute angle, spreading into an aponeurosis from which the muscle fibers arise; this aponeurosis is prolonged downward on the anterior surface of the muscle. The muscle ends in a broad and thick aponeurosis. This occupies the lower two-thirds

of its posterior surface, and it gradually becomes narrowed into a flattened tendon, which is inserted into the base of the patella.

The **vastus lateralis** is the largest component of the quadriceps femoris (Fig. 6-67). It arises by a broad aponeurosis from the proximal part of the intertrochanteric line, the anterior and inferior borders of the greater trochanter, the lateral lip of the gluteal tuberosity, and the proximal half of the lateral lip of the linea aspera. This aponeurosis covers the upper three-fourths of the muscle, and from its deep surface many additional fibers take origin. A few other fibers arise from the tendon of the *gluteus maximus* and from the lateral intermuscular septum between the *vastus lateralis* and short head of the *biceps femoris*. The fibers form a large fleshy mass, which is attached to a strong aponeurosis that lies on the deep surface of the distal part of the muscle. This aponeurosis becomes contracted and thickened into a flat tendon and is inserted into the lateral border of the patella, blending with the quadriceps femoris tendon and giving a tendinous expansion to the capsule of the knee joint.

The *vastus medialis* and *vastus intermedius* appear to be inseparably united, but when the *rectus femoris* has been reflected, a narrow cleft will be observed extending proximally from the medial border of the patella between the two muscles. The separation may be continued as far as the lower part of the intertrochanteric line, where, however, the two muscles are frequently fused.

The **vastus medialis** (Fig. 6-67) arises from the lower half of the intertrochanteric line, the medial lip of the linea aspera, the upper part of the medial supracondylar line, the tendons of the *adductor longus* and *adductor magnus*, and the medial intermuscular septum. Its fibers are directed downward and forward and are chiefly attached to an aponeurosis that lies on the deep surface of the muscle. The *vastus medialis* is inserted into the medial border of the patella and the quadriceps femoris tendon, and an expansion of the aponeurosis is sent to the capsule of the knee joint.

The **vastus intermedius** arises from the anterior and lateral surfaces of the upper two-thirds of the body of the femur and from the lower part of the lateral intermuscular septum. Its fibers end in an aponeurosis on

the anterior surface of the muscle, which forms the deep part of the quadriceps femoris tendon.

The **tendons** of the different portions of the quadriceps unite at the distal part of the thigh to form a single strong tendon that is inserted into the base of the patella, although a few fibers pass over it to blend with the ligamentum patellae. More properly, the patella may be regarded as a sesamoid bone, developed in the tendon of the quadriceps; the ligamentum patellae, which is continued from the apex of the patella to the tuberosity of the tibia, may be regarded as the proper tendon of insertion of the muscle, and the medial and lateral patellar retinacula as expansions from its borders. The **suprapatellar bursa**, which usually communicates with the cavity of the knee joint, is situated between the femur and the portion of the quadriceps tendon above the patella. The **deep infrapatellar bursa** is interposed between the tendon and the upper part of the anterior tibia. A third bursa, the **prepatellar bursa**, is placed superficial to the patella itself.

**Action.** The entire **quadriceps** muscle extends the leg at the knee joint. The **rectus femoris** also flexes the thigh at the hip joint. Additionally, the rectus femoris assists the iliopsoas muscle in flexing the trunk on the thigh.

**Nerves.** The quadriceps femoris is supplied by branches of the **femoral nerve**, containing fibers from the second, third, and fourth lumbar nerves.

**ARTICULARIS GENUS.** The articularis genus is a small muscle, usually distinct from the vastus intermedius but occasionally blended with it. It arises from the anterior surface of the lower part of the body of the femur and is inserted into the upper part of the synovial membrane of the knee joint. It sometimes consists of several separate muscular bundles.

**Action.** The **articularis genus** draws the synovial membrane of the knee joint upward as the leg is extended, thereby preventing folds of the membrane from being compressed within the joint.

**Nerve.** The articularis genus is supplied by fibers of the **femoral nerve** through its branch to the vastus intermedius muscle.

### Medial Femoral Muscles

Gracilis  
Pectineus

Adductor longus  
Adductor brevis  
Adductor magnus

**THE GRACILIS.** The gracilis, the most superficial muscle on the medial aspect of the thigh (Figs. 6-67; 6-69), is thin and flat, broad proximally, narrow and tapering distally. It arises by a thin aponeurosis from the lower part of the body of the pubis near the symphysis and from the adjoining pubic ramus. The fibers run vertically downward and end in a rounded tendon, which passes behind the medial condyle of the femur and then curves around the medial condyle of the tibia. At this site, it becomes flattened and is inserted into the upper part of the medial surface of the body of the tibia, below the tibial condyle. A few of the fibers of the distal part of the tendon are prolonged into the deep fascia of the leg. At its insertion the tendon is situated immediately above that of the semitendinosus, and its upper edge is overlapped by the tendon of the sartorius, with which it is in part blended. The tendons of insertion of the gracilis, sartorius, and semitendinosus blend to form a tendinous expansion called the **pes anserinus**. The **anserine bursa** lies between these tendons and the tibia.

**Action.** The **gracilis** adducts the thigh. It also flexes the leg at the knee and, after it is flexed, assists in its medial rotation.

**Nerve.** The gracilis is supplied by a branch of the anterior division of the **obturator nerve**, containing fibers from the second and third lumbar nerves.

**THE PECTINEUS.** The pectineus is a flat quadrangular muscle, situated at the anterior part of the upper and medial aspect of the thigh (Fig. 6-67). It arises from the pectineal pubis (pectineal line) and, to a slight extent, from the surface of bone anterior to it, between the iliopectineal eminence and the tubercle of the pubis. Some fibers also arise from the fascia covering the anterior surface of the muscle itself. The fibers pass downward, backward, and lateralward, to be inserted along a rough line leading from the lesser trochanter to the linea aspera.

**Action.** The **pectineus** flexes and adducts the thigh, and rotates it medially.

**Nerve.** The pectineus is usually supplied by a branch of the **femoral nerve**, containing fibers from

the second, third, and fourth lumbar nerves. When an **accessory obturator nerve** is present, one of its branches is distributed to the pectineus. The muscle may receive a branch from the **obturator nerve**.

**Variations.** The pectineus may consist of two incompletely separated strata. The lateral stratum is supplied by a branch of the femoral nerve or the accessory obturator, if present, and the medial stratum, when present, is supplied by the obturator nerve. The muscle may attach to the capsule of the hip joint.

**ADDUCTOR LONGUS.** This muscle is the most anterior of the three adductors, and it is triangular in shape and lies in the same plane as the pectineus (Fig. 6-71). It arises by a flat, narrow tendon from the anterior pubis, at the angle of junction of the crest with the symphysis, and soon expands into a broad fleshy belly. This passes downward, backward, and laterally to be inserted by an aponeurosis on the middle third of the femur along the linea aspera. Its insertion attaches between the origin of the vastus medialis and the insertion of the adductor magnus, muscles with which its fibers are usually blended.

**Action.** The **adductor longus** adducts, flexes, and tends to rotate the thigh medially.

**Nerve.** The adductor longus receives innervation from a branch of the anterior division of the

**obturator nerve**, containing fibers from the second, third, and fourth lumbar nerves.

**Variations.** The adductor longus may be doubled, it may extend to the knee, or it may be more or less united with the pectineus muscle.

**ADDUCTOR BREVIS.** The adductor brevis is situated immediately deep to the pectineus and adductor longus (Fig. 6-71). It is somewhat triangular in form and arises by a narrow attachment from the outer surface of the inferior ramus of the pubis, between the gracilis and obturator externus. Its fibers, passing backward, laterally, and downward, are inserted by an aponeurosis into the femur along a line leading from the lesser trochanter to the linea aspera and into the upper part of the linea aspera, immediately behind the pectineus and proximal part of the adductor longus.

**Action.** Similar to the adductor longus, the **adductor brevis** adducts, flexes, and tends to rotate the thigh medially at the hip joint.

**Nerve.** The adductor brevis is innervated by a branch of the **obturator nerve**, usually from its anterior division, containing fibers from the second, third, and fourth lumbar nerves.

**Variations.** The adductor brevis may be divided into two or three parts, or it may be united with the adductor magnus.

FIG. 6-70. Muscular insertions and bursae around the hip joint. (Raubert-Kopsch, 1955.)

FIG. 6-71. Deep muscles of the medial femoral region.

**ADDUCTOR MAGNUS.** The adductor magnus is a large triangular muscle, situated on the medial side of the thigh (Fig. 6-71). It arises from a small part of the inferior ramus of the pubis, from the inferior ramus of the ischium, and from the inferior and lateral

aspect of the tuberosity of the ischium. The fibers that arise from the ramus of the pubis are short and horizontal, and they are inserted into the rough line leading from the greater trochanter to the linea aspera, medial to the gluteus maximus. The **adductor minimus** is the name given to this part of the adductor magnus when it forms a distinct muscle. The fibers arising from the ramus of the ischium are directed downward and laterally, to be inserted by means of a broad aponeurosis into the linea aspera and the upper part of the medial supracondylar line. The medial portion of the muscle, composed principally of the fibers arising from the tuberosity of the ischium, forms a thick fleshy mass consisting of coarse bundles. These descend almost vertically and form, in the distal third of the thigh, a rounded tendon that is inserted into the adductor tubercle on the medial condyle of the femur. It is also connected by a fibrous expansion to the medial supracondylar line leading proximally from the tubercle to the linea aspera. Along the insertion of the muscle, there is a series of openings in the aponeurosis formed by tendinous arches attached to the bone. The upper four openings are small and give passage to the perforating branches of the profunda femoris artery. The lowest opening, called the **hiatus tendineus**, is large and transmits the femoral vessels to the popliteal fossa.

**Action.** The **adductor magnus** is a powerful adductor of the thigh. Its upper portion also weakly flexes and medially rotates the thigh, while the lower portion extends and laterally rotates the thigh.

**Nerves.** The adductor magnus is supplied by branches of the posterior division of the **obturator nerve**, containing fibers from the second, third, and fourth lumbar nerves, and by a branch from the **sciatic nerve**. The ischiocondylar portion, which is attached to the adductor tubercle, is derived from the flexor or hamstring muscles of lower forms and is the portion supplied by the sciatic nerve.

**Variations.** The adductor magnus may be fused with the quadratus femoris or with either the adductor longus or brevis.

### **Muscles of the Gluteal Region**

The muscles of the gluteal region are the principal extensors and lateral rotators of the thigh at the hip joint. They include the:

- Gluteus maximus
- Gluteus medius
- Gluteus minimus

Tensor fasciae latae  
Piriformis  
Obturator internus  
Gemellus superior  
Gemellus inferior  
Quadratus femoris  
Obturator externus

**GLUTEUS MAXIMUS.** The gluteus maximus is the largest and most superficial muscle in the gluteal region. It is a broad and thick fleshy mass, quadrilateral in shape, which forms the prominence of the buttocks (Fig. 6-72). Its large size is one of the most characteristic features of the human muscular system, connected as it is with the ability and power of maintaining the trunk in the erect posture. The muscle is remarkably coarse in structure, being composed of fasciculi lying parallel and collected into large bundles separated by fibrous septa. It arises from the posterior gluteal line of the ilium and the

rough portion of bone, including the crest, immediately superior and dorsal to it; from the posterior surface of the lower part of the sacrum and the side of the coccyx; from the aponeurosis of the erector spinae, the sacrotuberous ligament, and the fascia (gluteal aponeurosis) covering the gluteus medius. The fibers are directed obliquely downward and laterally. Those forming the upper and larger portion of the muscle, together with the superficial fibers of the lower portion, end in a thick tendinous lamina, which passes across the greater trochanter and is inserted into the iliotibial band of the fascia lata. The deeper fibers of the lower portion of the muscle are inserted into the gluteal tuberosity between the vastus lateralis and adductor magnus.

Three bursae are usually found in relation to the deep surface of this muscle. One of these, the **trochanteric bursa of the gluteus maximus**, is large and generally multilocu-

**Fig. 6-72.** The right gluteus maximus muscle.

lar, and separates the muscle from the greater trochanter. A second, the **ischial bursa of the gluteus maximus**, is often absent, but when present, it separates the muscle from the ischial tuberosity. A third bursa is found between the tendon of the muscle and that of the vastus lateralis.

**Action.** The **gluteus maximus** powerfully extends and laterally rotates the thigh at the hip joint, when its fixed site is the pelvis. Its upper fibers assist in abduction of the thigh, while the lower fibers adduct the thigh. It is relatively inactive when the limbs are motionless in standing or in easy normal walking, but it is very active in running or jumping. Acting by way of its attachment to the iliotibial tract, the gluteus maximus braces the fully extended knee. When the fixed site is at its insertion, the gluteus maximus extends the trunk on the lower extremity, as is necessary to rise from a sitting position or to climb stairs.

**Nerve.** The gluteus maximus is supplied by the **inferior gluteal nerve**, containing fibers from the fifth lumbar and first and second sacral nerves.

**GLUTEUS MEDIUS.** The gluteus medius is a broad, thick, radiating muscle, situated on the outer surface of the pelvis (Fig. 6-73). Its posteromedial third is covered by the gluteus maximus, its anterolateral two-thirds by the gluteal aponeurosis, which separates it from the superficial fascia and integument. It arises from the outer surface of the ilium between the iliac crest and posterior gluteal line dorsally, and the anterior gluteal line ventrally; it also arises from the gluteal aponeurosis covering its outer surface. The fibers converge in a fan-shaped manner to a strong, flattened tendon, which is inserted into the oblique ridge on the lateral surface of the greater trochanter. The **trochanteric bursa of the gluteus medius** separates the tendon of the muscle from the surface of the trochanter, over which it glides (Fig. 6-70).

**Action.** The **gluteus medius** is a strong abductor and medial (anterior fibers) rotator of the thigh. It is an important muscle (as is the gluteus minimus) in walking because it helps to maintain balance and an upright posture. As a foot is elevated from the ground with each step, all the body's weight is placed on the opposite limb, which should result in a marked sagging of the pelvis on the unsupported side. The action of the gluteus medius and minimus of the supported side prevents this tilting. If the gluteus medius and minimus are paralyzed, the trunk sways from side to side with each step in an attempt to prevent the downward tilting of the pelvis on the unsupported side.

**Fig. 6-73.** Muscles of the gluteal and posterior femoral regions.

**Nerve.** The gluteus medius is supplied by branches of the **superior gluteal nerve**, containing fibers from the fourth and fifth lumbar and first sacral nerves.

**Variation.** At times the posterior border of the gluteus medius is blended with the piriformis muscle.

**GLUTEUS MINIMUS.** The gluteus minimus, the smallest of the three glutei, is placed immediately deep to the gluteus medius (Fig. 6-71). It is fan-shaped, arising from the outer surface of the ilium, between the anterior and inferior gluteal lines, and behind the margin of the greater sciatic notch. The fibers converge to the deep surface of an aponeurosis, which then ends in a tendon that is inserted into an impression on the anterior border of the greater trochanter and gives an expansion to the capsule of the hip joint. The **trochanter bursa of the gluteus minimus** is interposed between the tendon and the greater trochanter. Separating the gluteus medius and gluteus minimus are the deep branches of the superior gluteal vessels and the superior gluteal nerve. Beneath the deep surface of the gluteus minimus is found the reflected tendon of the rectus femoris and the capsule of the hip joint.

**Action.** The gluteus minimus abducts and rotates the thigh medially. It also assists the gluteus medius during walking, as already described.

**Nerve.** The gluteus minimus is supplied by a branch of the **superior gluteal nerve**, containing fibers from the fourth and fifth lumbar and first sacral nerves.

**Variations.** The gluteus minimus may be divided into anterior and posterior parts, or it may send muscular slips to the piriformis, the superior gemellus, or the vastus lateralis.

**TENSOR FASCIAE LATAE.** The tensor fasciae latae (Fig. 6-67) arises from the anterior part of the outer lip of the iliac crest; from the outer surface of the anterior superior iliac spine, and part of the notch below it, between the gluteus medius and sartorius; and from the deep surface of the fascia lata. It is inserted between the two layers of the iliotibial tract of the fascia lata about at the junction of the middle and upper thirds of the thigh.

**Action.** The tensor fasciae latae flexes and abducts (and possibly rotates) the thigh. By contraction, it also tenses the iliotibial tract, thereby helping

to support the femur on the tibia during erect posture.

**Nerve.** The tensor fasciae latae is supplied by a branch of the **superior gluteal nerve** to the gluteus minimus, containing fibers from the fourth and fifth lumbar and first sacral nerves.

**THE PIRIFORMIS.** The piriformis is a flat muscle, pyramidal in shape, lying almost parallel with the posterior margin of the gluteus medius (Fig. 6-73). It is situated partly against the posterior wall on the interior of the pelvis (Fig. 6-74), and partly in the gluteal region behind the hip joint. The piriformis arises from the anterior sacrum by three fleshy digitations attached to the portions of bone between the first, second, third, and fourth anterior sacral foramina, and to the grooves leading from the foramina. A few fibers also arise from the margin of the greater sciatic foramen and from the anterior surface of the sacrotuberous ligament. The muscle passes out of the pelvis through the greater sciatic foramen, the upper part of which it fills. Coursing laterally, the piriformis is inserted by a rounded tendon into the superior border of the greater trochanter posterior to, but often partly blended with, the common tendon of the obturator internus and gemelli (Fig. 6-73).

**Action.** The piriformis laterally rotates the extended thigh. When the thigh is flexed, it abducts the femur. The piriformis assists in stabilizing the hip joint and helps to hold the femoral head in the acetabulum.

**Nerve.** The piriformis is supplied by either the **first or second sacral nerve**, but more frequently by branches from both nerves.

**Variations.** The piriformis is frequently pierced by the common peroneal nerve and, thus, becomes divided more or less into two parts. It may be united with the gluteus medius, or send fibers to the gluteus minimus, or receive fibers from the superior gemellus. The piriformis may have only one or two sacral attachments or be inserted into the capsule of the hip joint.

**OBTURATOR INTERNUS.** The obturator internus is situated both within the true or lesser pelvis (Fig. 6-74) and posterior to the hip joint (Fig. 6-73). It arises from the inner surface of the anterolateral wall of the pelvis where it surrounds the greater part of the obturator foramen. It is attached to the inferior rami of the pubis and ischium. Laterally it attaches to the inner pelvic surface, inferior to and behind the pelvic brim. It reaches

FIG. 6-74. The left obturator internus. Pelvic aspect.

from the upper part of the greater sciatic foramen above and behind, to the obturator foramen below and in front. It also arises from the pelvic surface of the obturator membrane except in the posterior part, from the tendinous arch that completes the canal for the passage of the obturator vessels and nerve, and to a slight extent from the obturator fascia, which covers the muscle. The fibers converge rapidly toward the lesser sciatic foramen and end in four or five tendinous bands on the deep surface of the muscle. These bands make a right angle bend around the grooved surface between the spine and tuberosity of the ischium. This bony surface is covered by smooth cartilage and serves as a pulley, being separated from the tendon by a bursa and presenting one or

more ridges corresponding with the furrows between the tendinous bands. These bands leave the pelvis through the lesser sciatic foramen and unite into a single flattened tendon. This passes horizontally across the capsule of the hip joint and, after receiving the attachments of the gemelli, is inserted into the anterior part of the medial surface of the great trochanter, proximal to the trochanteric fossa. The **subtendinous bursa of the obturator internus**, narrow and elongated in form, is usually found between the tendon and the capsule of the hip joint. It occasionally communicates with the bursa between the tendon and the ischium (**ischiodic bursa of the obturator internus**).

The **obturator membrane** (Fig. 5-31) is a thin fibrous sheet that almost completely

closes the obturator foramen. Its fibers are arranged in interlacing bundles, mainly transverse in direction. The superior bundle is attached to the obturator tubercles and completes the obturator canal for the passage of the obturator vessels and nerve. The membrane is attached to the sharp margin of the obturator foramen except at its inferior lateral angle, where it is fixed to the pelvic surface of the ramus of the ischium, i.e., within the margin. The two obturator muscles arise partly from the opposite surfaces of this membrane.

**Action.** The **obturator internus** rotates the extended thigh and abducts the thigh when it is flexed.

**Nerves.** The obturator internus is supplied by a special nerve from the sacral plexus, containing fibers from the lumbosacral trunk. The **nerve to the obturator internus** contains fibers from the fifth lumbar and the first and second sacral segments.

The **gemelli** are two small muscles that lie parallel with the tendon of the obturator internus after it emerges from the lesser sciatic foramen (Fig. 6-73).

**SUPERIOR GEMELLUS.** The superior gemellus is the smaller of the two. It arises from the outer surface of the spine of the ischium, blends with the upper part of the tendon of the obturator internus, and is inserted with it onto the medial surface of the greater trochanter.

**INFERIOR GEMELLUS.** The inferior gemellus arises from the tuberosity of the ischium, immediately below the groove for the obturator internus tendon. It blends with the lower part of the tendon of the obturator internus and is inserted with it into the medial surface of the greater trochanter.

**Action.** The **gemelli** rotate the extended thigh laterally and abduct the flexed thigh.

**Nerves.** The superior gemellus is supplied by a branch of the **nerve to the obturator internus**.

The inferior gemellus receives its innervation from a branch of the **nerve to the quadratus femoris**.

**Variations.** The gemelli may vary in size. The superior is more frequently absent, and the inferior is more frequently bound intimately to the obturator internus. The superior may be fused with the piriformis or gluteus minimus, the inferior with the quadratus femoris.

**QUADRATUS FEMORIS.** This small, flat, quadrilateral muscle is found between the gemellus inferior and the proximal margin

of the adductor magnus (Fig. 6-73). It is separated from the latter by the transverse branches of the medial femoral circumflex vessels. It arises from the upper part of the external border of the tuberosity of the ischium and, passing laterally, is inserted into a small tubercle (quadratus tubercle) found on the posterior aspect of the femur. The insertion continues distally for a short distance along the intertrochanteric crest. A bursa is often found between this muscle and the lesser trochanter.

**Action.** The **quadratus femoris** rotates the thigh laterally.

**Nerve.** The quadratus femoris is supplied by a special nerve, the **nerve to the quadratus femoris**, which contains fibers from the lumbosacral trunk (fourth and fifth lumbar) and first sacral nerves.

**Variations.** Absence of the quadratus femoris has been reported in 1 or 2%, but this may be more apparent than real because in these instances it is usually fused either with the gemellus inferior or the adductor magnus. It may be doubled at its insertion.

**OBTURATOR EXTERNUS.** The obturator externus is a flat, triangular muscle that covers the outer surface of the anterior wall of the pelvis (Fig. 6-75). It arises from the anterior aspect of the pelvis immediately around the medial side of the obturator foramen, that is, from the rami of the pubis and the ramus of the ischium. It also arises from the medial two-thirds of the outer surface of the obturator membrane and from the tendinous arch that completes the canal for the passage of the obturator vessels and nerves. A few fibers near the pubic arch arise from the inner surface of the pelvis between the margin of the foramen and the attachment of the obturator membrane. The fibers converge as they pass laterally and end in a tendon that courses behind the neck of the femur and the distal part of the capsule of the hip joint, to be inserted into the trochanteric fossa of the femur. The obturator vessels lie between the muscle and the obturator membrane. The anterior branch of the obturator nerve reaches the thigh by passing anterior to, or in front of, the muscle, and the posterior branch by piercing it.

**Action.** The **obturator externus** rotates the thigh laterally.

**Nerve.** The obturator externus is supplied by a branch of the **obturator nerve**, containing fibers from the third and fourth lumbar nerves. This branch

FIG. 6-75. The obturator externus.

comes either from the obturator nerve before it divides or from the posterior branch of the obturator after it divides.

**Group Muscle Actions at the Hip Joint.** *Extension of the thigh* is performed by the gluteus maximus and adductor magnus; the former is most powerful in a position of lateral rotation, the latter in medial rotation. The gluteus medius acts synergistically during extension to neutralize the adduction of the magnus and the lateral rotation of the gluteus maximus. The hamstring muscles can also extend the thigh, but are used for this action only if it accompanies flexion of the leg.

*Flexion of the thigh* is performed by the iliopsoas, tensor fasciae latae, pectineus, and sartorius. The action is initiated by the tensor, pectineus, and sartorius, but stronger and final action is by the iliopsoas, with assistance from the adductor muscles. The rectus femoris also flexes the hip, but only if the muscle is acting as an extensor at the knee.

*Abduction of the thigh* is principally performed by the gluteus medius and minimus. Some assistance in this action comes from the tensor fasciae latae and sartorius, and even from the obturator internus, piriformis, and lower fibers of the gluteus maximus.

*Adduction of the thigh* can result from the action of the three adductors, the pectineus, the obturator externus, the gracilis, and the hamstring muscles, as well as from the quadratus femoris and the upper fibers of the gluteus maximus.

*Lateral rotation of the thigh* is performed by the obturator externus and internus, gemelli, piriformis, quadratus femoris, gluteus maximus, posterior fibers of the gluteus medius, and sartorius. Electromyographic studies indicate that the iliopsoas muscle is also active during lateral rotation.

*Medial rotation of the thigh* is performed by the tensor fasciae latae, pectineus, gluteus minimus, and the lower fibers of the adductor magnus.

### Posterior Femoral Muscles

The posterior femoral muscles cross the hip and knee joints and act primarily as flexors of the leg at the knee joint and extensors of the thigh at the hip. They are frequently referred to as the hamstring muscles and include the:

Biceps femoris  
Semitendinosus  
Semimembranosus

**BICEPS FEMORIS.** The biceps femoris is situated on the posterior and lateral aspect of the thigh (Fig. 6-73). Its two heads of origin are called long and short. The **long head** arises from an inferomedial impression on the posterior part of the ischial tuberosity by a tendon in common with the semitendinosus muscle, and from the lower part of the sacrotuberous ligament. The **short head** does not cross the hip joint, but instead arises from the lateral lip of the linea aspera of the femur between the adductor magnus and vastus lateralis. It extends upward almost as high as the insertion of the gluteus maximus, and is prolonged down beyond the linea aspera to a point about 5 cm above the lateral condyle. It also arises from the lateral inter-

muscular septum. The fibers of the long head form a fusiform belly, which descends obliquely laterally across the sciatic nerve to end in an aponeurosis covering the posterior surface of the muscle. This aponeurosis receives on its deep surface the fibers of the short head. This aponeurosis becomes gradually contracted into a tendon, which is inserted into the lateral aspect of the head of the fibula, and a small tendinous slip, which attaches to the lateral condyle of the tibia. At its insertion the tendon divides into two portions, and these embrace the fibular collateral ligament of the knee joint. From the posterior border of the tendon a thin expansion extends to the fascia of the leg. The tendon of the biceps femoris forms the **lateral hamstring**, and the common peroneal nerve descends along its medial border.

**Action.** The biceps femoris flexes the leg and, after it is flexed, rotates the tibia laterally on the femur. The long head also extends the thigh and tends to rotate it laterally.

**Nerves.** The long head of the biceps femoris is supplied by branches, usually two, from the **tibial portion of the sciatic nerve**, containing fibers from the first three sacral nerves. The short head of the biceps femoris receives innervation from the peroneal portion of the sciatic nerve, containing fibers from the fifth lumbar and first two sacral nerves.

**Variations.** The short head of the biceps femoris may be absent. Additional heads may arise from the ischial tuberosity, the linea aspera, or the medial supracondylar ridge of the femur. A muscular slip may pass to the gastrocnemius.

**THE SEMITENDINOSUS.** The semitendinosus, remarkable because of the great length of its tendon of insertion, is situated at the posterior and medial aspect of the thigh (Fig. 6-73). It arises from the inferomedial impression of the ischial tuberosity by a tendon common to it and the long head of the biceps femoris. It also arises from an aponeurosis that connects the adjacent surfaces of the two muscles for an extent of about 7.5 cm from their origin. The muscle is fusiform and ends a little distal to the middle of the thigh in a long round tendon, which lies along the surface of the semimembranosus muscle, medial to the popliteal fossa. It then curves around the medial condyle of the tibia and passes over the tibial collateral ligament of the knee joint, from which it is separated by the anserine bursa. The tendon then is inserted into the proximal part of the

medial surface of the body of the tibia, nearly as far anteriorly as its anterior crest. At its insertion it gives off from its distal border a prolongation to the deep fascia of the leg. Lying posterior to the tendon of the sartorius and distal to that of the gracilis, the semitendinosus tendon unites with tendons of these other muscles to form a flattened aponeurosis known as the **pes anserinus**. A tendinous intersection is usually observed about the middle of the muscle.

**Action.** The semitendinosus flexes the leg and, after it is flexed, rotates the tibia medially. It also is able to extend the femur at the hip joint.

**Nerves.** The semitendinosus is supplied by the **tibial portion of the sciatic nerve** (usually by two branches), containing fibers from the fifth lumbar and first two sacral nerves.

**THE SEMIMEMBRANOSUS.** This muscle, so named because of its membranous tendon of origin, is situated at the back and medial side of the thigh (Fig. 6-73). It arises by a thick tendon from the upper and lateral impression on the ischial tuberosity adjacent to the origin of the biceps femoris and semitendinosus. The tendon of origin expands into an aponeurosis that covers the proximal part of the anterior surface of the muscle. From this aponeurosis, muscular fibers arise and converge to another aponeurosis. The latter aponeurosis covers the distal part of the posterior surface of the muscle, which then becomes the tendon of insertion. The semimembranosus is inserted mainly into the horizontal groove on the posteromedial aspect of the medial condyle of the tibia. The tendon of insertion gives off a number of fibrous expansions; one, of considerable size, passes upward and laterally to be inserted into the posterior aspect of the lateral condyle of the femur, forming part of the oblique popliteal ligament of the knee joint. Another is continued distally to the fascia that covers the popliteus muscle, while a few fibers join the tibial collateral ligament of the joint and the fascia of the leg. The muscle overlaps the proximal part of the popliteal vessels. The tendons of the semitendinosus and semimembranosus form the **medial hamstrings**.

**Action.** The semimembranosus flexes the leg and, after it is flexed, tends to rotate it medially. It also extends the thigh at the hip joint.

**Nerves.** The semimembranosus is supplied by

several branches from the **tibial portion of the sciatic nerve**, containing fibers from the fifth lumbar and first two sacral nerves.

**Variations.** The semimembranosus may be reduced, absent, or doubled. It may arise primarily from the sacrotuberous ligament and give a slip to the femur or adductor magnus muscle.

**Group Actions at the Knee.** *Extension of the leg* is performed by the quadriceps femoris, i.e., the rectus femoris, vastus lateralis, vastus medialis, and vastus intermedius.

*Flexion of the leg* is performed by the hamstring muscles, i.e., the biceps femoris, semitendinosus, and semimembranosus, and by the popliteus. The sartorius and gracilis act in full flexion and against resistance. The gastrocnemius may assist in flexion of the leg, but is used more to protect the knee joint from hyperextension.

*Lateral rotation of the leg*, when the knee is partially flexed, is performed by the biceps femoris muscle.

*Medial rotation of the leg* is performed by the gracilis and popliteus. The semimembranosus and semitendinosus also can act as medial rotators of the partially flexed leg.

## MUSCLES AND FASCIAE OF THE LEG

The portion of the lower limb between the knee and ankle joints is known as the **leg**. Attached to its bones, the **tibia** and **fibula**, are three groups of muscles—**anterior**, **posterior**, and **lateral**.

The superficial fascia covering the leg is both fatty and fibrous, and coursing through it are the cutaneous nerves and superficial vessels. Continuous with the superficial fascia of the thigh above and the foot below, this fascia can be dissected rather easily from the underlying deep fascia.

**DEEP FASCIA OF THE LEG.** Also known as the **crural fascia**, the deep fascia of the leg forms a complete investment for the muscles and becomes fused with the periosteum over the subcutaneous surfaces of the bones. It is continuous superiorly with the fascia lata, and is attached around the knee to the patella, the patellar ligament, the condyles of the femur, the tuberosity and condyles of the tibia, and the head of the fibula. *Posteriorly*, it forms the **popliteal fascia**, covering the popliteal fossa, where it is strengthened by transverse fibers and perforated by the small saphenous vein. *Medially*, at the knee, the crural fascia receives expansions from the tendons of the sartorius, gracilis, semitendinosus, and semimembranosus, while *later-*

*ally*, at the knee, it receives an expansion from the tendon of the biceps femoris muscle. The deep fascia blends *anteriorly* with the periosteum covering the subcutaneous surface of the tibia; *inferolaterally*, with the periosteum covering the head and malleolus of the fibula. *Inferiorly*, the crural fascia is continuous with the superior extensor retinaculum and flexor retinaculum. It is thick and dense in the upper anterior part of the leg, and gives attachment by its deep surface to the tibialis anterior and extensor digitorum longus muscles. In the mid-posterior aspect of the calf, it is thinner where it covers the gastrocnemius and soleus. It gives off from its deep surface, on the lateral aspect of the leg, two strong intermuscular septa, the **anterior** and **posterior crural intermuscular septa**, which enclose the peroneus longus and brevis muscles and separate them from the muscles of the anterior and posterior crural regions. Other septa in the anterior and posterior crural regions separate the individual muscles. A broad transverse intermuscular septum, called the **deep transverse fascia of the leg**, intervenes between the superficial and deep posterior crural muscles.

The muscles of the leg will be described in three groups:

- Anterior crural
- Posterior crural
- Lateral crural

### **Anterior Crural Muscles**

The anterior crural muscles occupy the **anterior compartment** of the leg, which lies between the tibia and the anterior intermuscular septum. The four muscles of this compartment are:

- Tibialis anterior
- Extensor hallucis longus
- Extensor digitorum longus
- Peroneus tertius

**TIBIALIS ANTERIOR.** The tibialis anterior muscle, situated on the lateral aspect of the tibia, is thick and fleshy proximally, but tendinous distally (Fig. 6-76). It arises from the lateral condyle and upper half or two-thirds of the lateral surface of the body of the tibia; from the adjoining part of the interosseous membrane; from the deep surface of the crural fascia; and from an intermuscular sep-

FIG. 6-76. Muscles of the anterior leg.

tum between it and the extensor digitorum longus. The fibers course vertically downward to end in a tendon that becomes apparent on the anterior surface of the muscle along the lower third of the leg. After passing through the most medial compartments of the superior and inferior extensor retinacula, it is inserted into the medial and plantar surfaces of the medial cuneiform bone, and the base of the first metatarsal bone. This muscle overlaps the anterior tibial vessels and deep peroneal nerve in the proximal part of the leg.

**Action.** The *tibialis anterior* dorsally flexes the foot at the talocrural joint. It also inverts and adducts (supinates) the foot at the subtalar and midtarsal joints. These actions are especially important as the foot leaves the ground during walking and running.

**Nerve.** The *tibialis anterior* is supplied by a branch of the **deep peroneal nerve**, containing fibers from the fourth and fifth lumbar and first sacral nerves.

**Variations.** In rare instances, a deep portion of the *tibialis anterior* muscle is inserted into the talus, or a tendinous slip may pass to the head of the first metatarsal bone or the base of the proximal phalanx of the great toe. The **tibiofascialis anterior** is a small muscle sometimes seen extending from the distal part of the tibia to the superior or inferior extensor retinacula or deep fascia.

**EXTENSOR HALLUCIS LONGUS.** The extensor hallucis longus is a thin muscle, situated between the *tibialis anterior* and the *extensor digitorum longus*. Its muscular belly is largely covered by these two muscles, and its tendon emerges to a superficial position in the lower third of the leg (Fig. 6-76). The *extensor hallucis longus* arises from the medial surface of the fibula along the middle two-fourths of its extent, medial to the origin of the *extensor digitorum longus*, and from the interosseous membrane. The anterior tibial vessels and deep peroneal nerve lie between it and the *tibialis anterior*. The fibers descend and end in a tendon that occupies the anterior border of the muscle. It then passes deep to the superior extensor retinaculum, through a distinct compartment in the inferior extensor retinaculum, crosses from the lateral to the medial side of the anterior tibial vessels near the talocrural joints, and is inserted into the base of the distal phalanx of the great toe. Opposite the metatarsophalangeal articulation, the tendon gives off a

thin prolongation on both sides to cover the dorsal surface of the joint. An expansion from the medial side of the tendon is usually inserted into the base of the proximal phalanx.

**Action.** The **extensor hallucis longus** extends the proximal phalanx of the great toe. It also dorsally flexes and supinates the foot.

**Nerve.** The extensor hallucis longus is supplied by a branch of the **deep peroneal nerve**, containing fibers from the fourth and fifth lumbar and first sacral nerves.

**Variations.** The origin of the extensor hallucis longus is occasionally united with that of the extensor digitorum longus. The **extensor ossis metatarsi hallucis** is a small muscle that is sometimes found as a slip from the extensor hallucis longus, or from the tibialis anterior, or from the extensor digitorum longus, or as a distinct muscle traversing the same compartment of the superior extensor retinaculum as the extensor hallucis longus.

**EXTENSOR DIGITORUM LONGUS.** The extensor digitorum longus is a penniform muscle situated in the lateral part of the anterior leg (Figs. 6-76; 6-79). It arises from the lateral condyle of the tibia, from the upper three-fourths of the anterior surface of the body of the fibula, from the proximal part of the interosseous membrane, from the deep surface of the fascia, and from the intermuscular septa between it and the tibialis anterior on the medial aspect and the peroneal muscles on the lateral aspect. Between the extensor digitorum longus and the tibialis anterior in the upper leg are the proximal portions of the anterior tibial vessels and deep peroneal nerve. The tendon passes beneath the superior and inferior extensor retinacula in company with the peroneus tertius. It then divides into four slips, which course forward on the dorsum of the foot and are inserted into the middle and distal phalanges of the four lesser toes. The tendons to the second, third, and fourth toes are each joined laterally, opposite the metatarsophalangeal articulation, by a tendon of the extensor digitorum brevis. Each of the tendons receives a fibrous expansion from the interossei and lumbricals before spreading outward into a broad aponeurosis called the digital extensor hood, which covers the dorsal surface of the proximal phalanx. This aponeurosis, at the articulation of the proximal with the middle phalanx, divides into three slips—an intermediate, which is inserted into the base

of the middle phalanx, and two collateral slips, which, after uniting on the dorsal surface of the middle phalanx, are continued onward, to be inserted into the base of the distal phalanx (Fig. 6-76).

**Action.** The **extensor digitorum longus** extends the proximal phalanges of the four lateral toes. It also dorsally flexes and everts (tends to pronate) the foot.

**Nerve.** The extensor digitorum longus is supplied by branches of the **deep peroneal nerve**, containing fibers from the fourth and fifth lumbar and first sacral nerves.

**Variations.** The extensor digitorum longus muscle varies considerably in its mode of origin and in the arrangement of its various tendons. The tendons to the second and fifth toes may be doubled, or extra slips may be given off from one or more tendons to their corresponding metatarsal bones, to the short extensor, or to one of the interosseous muscles. A slip to the great toe from the innermost tendon has also been reported.

**PERONEUS TERTIUS.** The peroneus tertius (Figs. 6-76; 6-79) is part of the extensor digitorum longus and might be described as its fifth tendon. The muscle fibers attaching to this tendon arise from the distal third or more of the anterior surface of the fibula, from the distal part of the interosseous membrane, and from an intermuscular septum between it and the peroneus brevis. The tendon, after passing deep to the superior and inferior extensor retinacula in the same canal as the extensor digitorum longus, is inserted into the dorsal surface of the base of the metatarsal bone of the little toe (Fig. 6-80).

**Action.** The **peroneus tertius** dorsally flexes and assists in everting the foot.

**Nerve.** The peroneus tertius is supplied by a branch of the **deep peroneal nerve**, containing fibers from the fifth lumbar and first sacral nerves.

### Posterior Crural Muscles

The muscles of the posterior leg are subdivided into two groups—superficial and deep. Those of the superficial group constitute a powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and this size bears a direct relation to his erect posture and his mode of locomotion.

**SUPERFICIAL GROUP**

Gastrocnemius  
Soleus  
Plantaris

The two heads of the gastrocnemius and the soleus muscle are collectively called the **triceps surae**. Its common tendon of insertion is the **tendo calcaneus**, more popularly known as the Achilles' tendon.

**THE GASTROCNEMIUS.** The gastrocnemius is the most superficial muscle of the calf (Fig. 6-77). Forming the prominent contour of the posterior leg, it arises by two heads and these are connected to the condyles of the femur by strong, flat tendons. The **medial head**, the larger of the two, arises from a depression at the upper and posterior part of the medial condyle and from the adjacent popliteal surface of the femur above the medial condyle. The **lateral head** arises from an impression on the side of the lateral condyle and from the posterior surface of the femur immediately above the lateral part of the condyle. Both heads also arise from the subjacent part of the capsule of the knee joint. Each tendon spreads out into an aponeurosis that covers the posterior surface of the respective head. From the anterior surfaces of these tendinous expansions, muscular fibers arise, those of the medial head being thicker and extending more distally than those of the lateral. The fibers unite at an angle in the midline of the muscle, forming a tendinous raphe that expands into a broad aponeurosis on the anterior surface of the muscle. Into this raphe the remaining fibers are inserted. The aponeurosis, gradually contracting, unites with the tendon of the soleus and forms with it the **tendo calcaneus**.

**Action.** The gastrocnemius plantar flexes the foot (points the toe), flexes the leg, and tends to supinate the foot.

**Nerves.** The gastrocnemius is supplied by branches of the **tibial nerve**, containing fibers from the first and second sacral nerves.

**Variations.** Absence of the lateral head or of the entire muscle has been observed. An extra slip from the popliteal surface of the femur is a more frequent variation.

**THE SOLEUS.** The soleus muscle is broad and flat and lies immediately deep to the gastrocnemius (Figs. 6-77; 6-79). It arises by tendinous fibers from the posterior surface

of the head of the fibula, from the proximal third of the posterior surface of the body of the fibula, from the soleal line, and from the middle third of the medial border of the tibia. Some fibers also arise from a tendinous arch placed between the tibial and fibular origins of the muscle, under which the popliteal vessels and tibial nerve run.

**Fig. 6-77.** Muscles of the posterior compartment of the leg. Superficial layer.

The fibers end in an aponeurosis, which covers the posterior surface of the muscle. This aponeurosis gradually becomes thicker and narrower and joins the insertion of the gastrocnemius to form with it the **tendo calcaneus**.

**Action.** The **soleus** muscle plantar flexes the foot, but it is an important postural muscle as well, appearing to be constantly active during ordinary quiescent standing. Because the center of gravity of the body passes anterior to the ankle joints, this muscle helps to prevent the body from falling forward.

**Nerve.** The soleus is supplied by a branch of the **tibialis nerve**, containing fibers from the first and second sacral nerves.

**Variations.** At times an accessory head is seen at its lower and inner part, usually ending in the **tendo calcaneus**, the **calcaneus**, or the **flexor retinaculum**.

**TENDO CALCANEUS.** The calcaneal tendon (also called the tendon of Achilles) is the common tendon of the gastrocnemius and soleus and is the thickest and strongest in the human body (Figs. 6-77; 6-79). It is about 15 cm long and begins near the middle of the leg, but its anterior surface receives fleshy fibers almost to its distal end. It gradually contracts as it descends, so that it is rounded and narrowest at a point about 4 cm above its insertion. Below this it expands once again, spreading somewhat to insert into the middle part of the posterior surface of the calcaneus. The **calcaneal subtendinous bursa** is interposed between the tendon and the bone. It is covered by the fascia and the integument, and it is separated from the deep muscles and vessels by a considerable interval that is filled with areolar and adipose tissue. Along its lateral aspect, but superficial to it, is the small saphenous vein.

**THE PLANTARIS.** The plantaris is a small muscle placed between the gastrocnemius and soleus (Figs. 6-77; 6-79). It arises from the distal part of the lateral prolongation of the **linea aspera** and from the oblique popliteal ligament of the knee joint. It forms a small fusiform belly, from 7 to 10 cm long, ending in a long slender tendon that crosses obliquely between the gastrocnemius and soleus and runs along the medial border of the **tendo calcaneus**, to be inserted with it into the posterior part of the calcaneus. This muscle is sometimes doubled, and at other times wanting. Occasionally, its tendon

fuses with the **flexor retinaculum** or with the fascia of the leg. The plantaris is a rudimentary muscle and is frequently compared to the **palmaris longus** in the forearm.

**Action.** The **plantaris** is a weak flexor of the leg at the knee joint and plantar flexor of the foot at the ankle joint.

**Nerve.** The plantaris is supplied by a branch of the **tibial nerve**, containing fibers from the fourth and fifth lumbar and first sacral nerves.

## DEEP GROUP

Popliteus  
Flexor hallucis longus  
Flexor digitorum longus  
Tibialis posterior

**DEEP TRANSVERSE FASCIA.** The deep transverse fascia is an intermuscular fibrous septum that stretches across the posterior leg between the superficial and deep posterior crural muscles. Extending transversely, it is connected at the sides to the margins of the tibia and fibula. Above, where it covers the popliteus muscle, it is thick and dense, and receives an expansion from the tendon of the **semimembranosus**. It is thinner in the middle of the leg, but distally, where it covers the tendons passing behind the malleoli, it is thickened and continuous with the **flexor retinaculum**.

**THE POPLITEUS.** The popliteus is a thin, flat, triangular muscle that forms the distal part of the floor of the popliteal fossa. The lateral portion of the muscle arises by a strong tendon about 2.5 cm long, from a depression at the anterior part of the groove on the lateral condyle of the femur. Its more medial fibers arise from the arcuate popliteal ligament and the capsule of the knee joint. The muscle descends across the upper leg to insert into the medial two-thirds of the triangular surface proximal to the soleal line on the posterior surface of the tibia, and into the tendinous expansion covering the surface of the muscle.

**Action.** The **popliteus** flexes and medially rotates the leg. More importantly, however, when the tibia is fixed, as occurs when the limb is supporting weight, the popliteus rotates the femur laterally on the tibia to "unlock" the knee joint.

**Nerve.** The popliteus is supplied by a branch of the **tibial nerve**, containing fibers from the fourth and fifth lumbar and first sacral nerves.

**Variations.** An additional slip of the popliteus muscle may arise from the sesamoid bone in the lateral head of the gastrocnemius. More rarely, a **popliteus minor** muscle arises from the femur on the inner side of the plantaris and inserts into the posterior ligament of the knee joint. In 14% of limbs, a muscle arises on the inner side of the head of the fibula and inserts into the upper end of the oblique line of the tibia, lying beneath the popliteus muscle.

**FLEXOR HALLUCIS LONGUS.** The flexor hallucis longus is situated on the fibular side of the leg (Fig. 6-78). It arises from the inferior two-thirds of the posterior surface of the body of the fibula (except the most distal 2.5 cm), from the distal part of the interosseous membrane, from an intermuscular septum between the flexor hallucis longus and the peronei, laterally, and from the fascia covering the tibialis posterior, medially. The fibers pass obliquely downward, ending in a tendon that occupies nearly the whole length of the posterior surface of the muscle. This tendon lies in a groove that crosses the posterior surface of the lower end of the tibia, the posterior surface of the talus, and the inferior surface of the sustentaculum tali of the calcaneus. In the sole of the foot it runs forward between the two heads of the flexor hallucis brevis and is inserted into the base of the terminal phalanx of the large toe. The grooves on the talus and calcaneus, which contain the tendon of the muscle, are converted by tendinous fibers into distinct canals, lined by a synovial sheath. As the tendon courses distally in the sole of the foot, it passes beneath the tendon of the flexor digitorum longus to which it is connected by a strong tendinous slip.

**Action.** The **flexor hallucis longus** flexes the distal phalanx of the great toe. It plantar flexes and supinates the foot, and it importantly contributes to the propulsion of the foot at its "take off" during walking and running.

**Nerve.** The flexor hallucis longus is supplied by a branch of the **tibial nerve**, containing fibers from the fifth lumbar and first and second sacral nerves.

**Variations.** The flexor hallucis longus usually sends a slip to the flexor digitorum longus, and frequently an additional slip courses from the flexor digitorum longus to the flexor hallucis. On rare occasions, an aberrant muscle, the **peroneocalcaneus internus**, takes origin below or lateral to the flexor hallucis longus from the posterior aspect of the fibula, passes under the sustentaculum tali with the flexor hallucis longus, and inserts on the calcaneus.

**FIG. 6-78.** Muscles of the posterior compartment of the leg. Deep layer.

**FLEXOR DIGITORUM LONGUS.** The flexor digitorum longus, situated on the tibial side of the leg, is thin and pointed at its origin, but it gradually increases in size as it descends (Fig. 6-78). It arises from the posterior surface of the body of the tibia, medial to the

origin of the tibialis posterior. Its attachment extends from immediately below the soleal line to within 7 or 8 cm of the lower tibial extremity. It also arises from the fascia covering the tibialis posterior. The fibers end in a tendon that extends nearly the entire length of the posterior surface of the muscle. The tendon passes behind the medial malleolus in a groove common to it and the tendon of the tibialis posterior, but separated from the latter by a fibrous septum. Each tendon is contained in a special compartment lined by a separate synovial sheath. The tendon of the flexor digitorum longus passes obliquely downward and laterally, superficial to the deltoid ligament of the ankle joint, into the sole of the foot (Fig. 6-81), where it crosses superficial to the tendon of the flexor hallucis longus, from which it receives a strong tendinous slip. It then expands, is joined by the quadratus plantae muscle, and finally divides into four tendons, which are inserted into the bases of the distal phalanges of the second, third, fourth, and fifth toes, each tendon passing through an opening in the corresponding tendon of the flexor digitorum brevis opposite the base of the proximal phalanx.

**Action.** The flexor digitorum longus flexes the terminal phalanges of the four small toes, thereby allowing them to grip the ground more securely during walking. It also plantar flexes and supinates the foot at the ankle joint.

**Nerve.** The flexor digitorum longus is supplied by a branch of the **tibial nerve**, containing fibers from the fifth lumbar and first sacral nerves.

**Variations.** Not infrequently, a muscular slip called the **flexor accessorius longus digitorum** arises from the fibula, tibia, or deep fascia and ends in a tendon that passes deep to the flexor retinaculum and joins the tendon of the flexor digitorum longus or the quadratus plantae tendon.

**TIBIALIS POSTERIOR.** The tibialis posterior lies between the flexor digitorum longus and the flexor hallucis longus in the upper half of the leg, and it is the most deeply situated muscle in this flexor group (Fig. 6-78). The proximal end of the muscle consists of two pointed processes, separated by an angular interval through which the anterior tibial vessels pass to the anterior leg. It arises from the whole of the posterior surface of the interosseous membrane, except its lowest part; from the lateral portion of the posterior surface of the body of the tibia, between the

commencement of the soleal line proximally and the junction of the middle and lower thirds of the tibial shaft distally; and from the proximal two-thirds of the medial surface of the fibula. Some fibers also arise from the deep transverse fascia, and from the intermuscular septa separating it from the adjacent muscles. In the lower one-fourth of the leg, its tendon passes anterior, that is, deep, to that of the flexor digitorum longus and lies with it in a groove behind the medial malleolus, but enclosed in a separate sheath. It next passes deep to the flexor retinaculum and superficial to the deltoid ligament. As it enters the foot, it turns forward superficial to the plantar calcaneonavicular ligament, and at this site the tendon contains a sesamoid fibrocartilage. It is inserted into the tuberosity of the navicular bone and gives off fibrous expansions, one of which passes backward to the sustentaculum tali of the calcaneus, while others course distally and laterally to the three cuneiforms, the cuboid, and the bases of the second, third, and fourth metatarsal bones.

**Action.** When the foot is not bearing weight, the **tibialis posterior** is a plantar flexor of the foot. Because it also attaches to the lateral tarsal bones, it inverts and adducts (tends to supinate) the foot as well. When the foot is bearing weight, as in standing or walking, the tibialis posterior, along with other leg muscles, helps to distribute weight on the foot, thereby assisting in maintaining balance.

**Nerve.** The tibialis posterior is supplied by the **tibial nerve**, containing fibers from the fifth lumbar and first sacral nerves.

### **Lateral Crural Muscles**

The lateral crural muscles, two in number, occupy the lateral compartment of the leg, and they arise from the external surface of the fibula. They are separated from the anterior and posterior crural muscles by the anterior and posterior intermuscular septa. Innervated by the superficial peroneal nerve, these muscles act as everters of the nonweight-bearing foot. The two lateral crural muscles are:

Peroneus longus  
Peroneus brevis

**PERONEUS LONGUS.** The peroneus longus is situated proximally on the lateral aspect of the leg and is the more superficial of the

two muscles. It arises from the head and upper two-thirds of the lateral surface of the body of the fibula, from the deep surface of the fascia, and from the intermuscular septa between it and the muscles on the anterior and posterior leg. Occasionally, a few fibers also arise from the lateral condyle of the tibia. Between its attachments to the head and to the body of the fibula, there is a gap through which the common peroneal nerve passes to the anterior leg. The peroneus longus ends in a long tendon, which runs behind the lateral malleolus, in a groove common to it and the tendon of the peroneus brevis, behind which it lies. The groove is converted into a canal by the superior peroneal retinaculum, the tendons being contained in a common synovial sheath. The tendon of the peroneus longus then extends obliquely forward across the lateral aspect of the calcaneus, below the peroneal trochlea and the tendon of the peroneus brevis, and under cover of the inferior peroneal retinaculum. It crosses the lateral aspect of the cuboid, and then runs on the plantar surface of that bone in a groove that is converted into a canal by the long plantar ligament. The tendon then crosses the sole of the foot obliquely, and is inserted into the lateral aspect of the base of the first metatarsal bone and the lateral aspect of the medial cuneiform. Occasionally, it sends a slip to the base of the second metatarsal bone. The tendon of the peroneus longus changes direction at two points: first, behind the lateral malleolus; second, on the cuboid bone. At both sites the tendon is thickened, and along the cuboid bone a sesamoid fibrocartilage, which sometimes ossifies, is usually developed in its substance.

**Action.** The *peroneus longus* everts and, at the same time, abducts the foot in an action referred to as pronation. It may also act as a weak plantar flexor of the foot. During normal standing the muscle does not appear to be active, but is importantly involved as the foot takes off from the ground during walking. Additionally, the oblique course of the tendon across the plantar aspect of the foot helps to maintain the integrity of the lateral longitudinal and transverse arches of the foot.

**Nerve.** The *peroneus longus* is supplied by a branch of the **superficial peroneal nerve** that contains fibers from the fourth and fifth lumbar and first sacral nerves.

**PERONEUS BREVIS.** The *peroneus brevis* lies under cover of the *peroneus longus* and is a shorter and smaller muscle. It arises from the distal two-thirds of the lateral surface of the body of the fibula, its upper fibers being anterior to the lower fibers of the *peroneus longus*. It also arises from the intermuscular septa separating it from the adjacent muscles on the anterior and posterior leg. The fibers pass vertically downward, ending in a tendon that courses behind the lateral malleolus, along with but anterior to that of the *peroneus longus*. The two tendons are enclosed in the same compartment and are lubricated by a common synovial sheath. The *peroneus brevis* then turns forward on the lateral aspect of the calcaneus, above the peroneal trochlea and the tendon of the *peroneus longus*, and is inserted into the tuberosity at the base of the fifth metatarsal bone, on its lateral aspect.

On the lateral surface of the calcaneus, the tendons of the *peroneus longus* and *peroneus brevis* occupy separate osseoponeurotic canals formed by the calcaneus and the inferior peroneal retinaculum. Each tendon is enveloped by an individual distal prolongation of the common synovial sheath.

**Action.** The *peroneus brevis* everts and abducts (pronates) the foot. It also acts as a plantar flexor of the foot at the ankle joint. During walking, it compensates for inversion, thereby helping to balance the foot in order to support properly the weight of the body.

**Nerve.** The *peroneus brevis* is supplied by a branch of the **superficial peroneal nerve** that contains fibers from the fourth and fifth lumbar and first sacral nerves.

**Variations.** Fusion of the two *peroneus* muscles is rare. A slip from the *peroneus longus* to the base of the third, fourth, or fifth metatarsal bone, or to the adductor hallucis, is occasionally seen. Several additional muscle variants have been described:

1. *Peroneus accessorius* arises from the fibula between the *longus* and *brevis*, and joins the tendon of the *longus* in the sole of the foot.

2. *Peroneus digiti minimi* is rare, but when present arises from the lower fourth of the fibula under the *brevis* and inserts into the extensor aponeurosis of the little toe. It is more common as a slip of the tendon of the *peroneus brevis*.

3. *Peroneus quartus* is present in about 13% of specimens and arises from the back of the fibula between the *brevis* and the *flexor hallucis* to insert into the peroneal trochlea of the calcaneum (**peroneocalcaneus externum**) or, less frequently into the tuberosity of the cuboid (**peroneocuboideus**).

**Group Actions at the Ankle.** *Plantar flexion of the foot* is brought about by the gastrocnemius, soleus, plantaris, peroneus longus and brevis, and tibialis posterior. The peronei and tibialis posterior act alone if there is no resistance to be overcome, whereas the flexor digitorum longus and flexor hallucis longus come into action to counter resistance.

*Dorsal flexion of the foot* is performed by the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius. The peroneus brevis, along with the extensor digitorum longus and peroneus tertius, acts to neutralize the inversion of the tibialis anterior and extensor hallucis longus.

*Supination of the foot* (combined adduction and inversion) is performed principally by the tibialis anterior and tibialis posterior. The tibialis posterior adducts more powerfully, whereas the tibialis anterior inverts more powerfully. The gastrocnemius also tends to supinate the foot.

*Pronation of the foot* (combined abduction and eversion) is performed by the peronei. The peroneus brevis abducts more strongly and acts slightly before the longus, whereas the peroneus longus everts more strongly. The peroneus tertius also tends to pronate as does the extensor digitorum longus.

### **Fascia Around the Ankle**

Embedded in or fused with the deep fascia of the lower leg are fibrous bands that form retinacula and bind down the tendons as they cross the ankle joint in their passage into the foot. These fibrous bands are more distinct in some bodies than in others. Generally, however, there are (1) two retinacula binding the extensor muscles, the **superior and inferior extensor retinacula**; (2) one retinaculum located medially over the flexor tendons, the **flexor retinaculum**; and (3) two retinacula located laterally over the tendons of the peroneal muscles, the **superior and inferior peroneal retinacula**.

**SUPERIOR EXTENSOR RETINACULUM.** The superior extensor retinaculum (Figs. 6-76; 6-79; 6-80), also known as the *transverse crural ligament*, binds down the tendons of the tibialis anterior, extensor hallucis longus, extensor digitorum longus, and peroneus tertius just above the anterior aspect of the ankle joint. Coursing with the tendons as they enter the foot deep to the retinaculum are the anterior tibial vessels and deep peroneal nerve. This retinaculum is attached laterally to the distal end of the fibula, and medially to the tibia, and at this site only the tendon of the tibialis anterior has a synovial sheath.

**INFERIOR EXTENSOR RETINACULUM.** The inferior extensor retinaculum (Figs. 6-76; 6-79 to 6-81), which is also called the *cruciate crural ligament*, is a Y-shaped band placed anterior to the ankle joint. The stem of the Y is attached laterally to the upper surface of the calcaneus, adjacent to the calcaneal sulcus, which contains the interosseous talocalcaneal ligament. It is directed medially as a double layer, which surrounds the tendons of the peroneus tertius and the extensor digitorum longus, one layer passing superficial to the tendons, the other deep to them. At the medial border of the extensor digitorum longus, the two layers join to form a compartment in which the tendons are enclosed. Continuing medially, the retinaculum diverges to form the two limbs of the Y. The *upper band* is directed proximally and medially to be attached to the medial malleolus. It passes superficial to the tendon of the extensor hallucis longus, the anterior tibial vessels, and the deep peroneal nerve, but encloses the tibialis anterior by a splitting of its fibers. The *lower band* extends distally and medially, to be attached to the border of the plantar aponeurosis. It passes superficial to the tendons of the extensor hallucis longus and tibialis anterior and also the dorsalis pedis artery and deep peroneal nerve.

**FLEXOR RETINACULUM.** The flexor retinaculum (Fig. 6-81) has also been called the *lacinate ligament*. It is a strong fibrous band that extends from the medial malleolus of the tibia proximally, to the margin of the calcaneus distally, where it converts a series of bony grooves into canals for the passage of the tendons of the flexor muscles, the posterior tibial vessels, and the tibial nerve into the sole of the foot. Its upper border is continuous with the deep fascia of the leg, and its lower border blends with the plantar aponeurosis and the fibers of the origin of the abductor hallucis muscle. From medial to lateral, the four canals formed by the flexor retinaculum transmit: (1) the tendon of the tibialis posterior, (2) the tendon of the flexor digitorum longus, (3) the posterior tibial vessels and tibial nerve, which course through a broad space beneath the ligament, and (4) in a canal formed partly by the talus, the tendon of the flexor hallucis longus.

**SUPERIOR PERONEAL RETINACULUM.** The superior peroneal retinaculum (Fig. 6-79) binds down the tendons of the peroneus

**FIG. 6-79.** Muscles of the right leg, viewed from the lateral aspect. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban & Schwarzenberg, 11th Ed., Vol. 1, 1975.)

**FIG. 6-80.** The synovial sheaths of the tendons around the ankle. Lateral aspect.

**FIG. 6-81.** The synovial sheaths of the tendons around the ankle. Medial aspect.

longus and peroneus brevis as they course around the lateral aspect of the ankle. The fibers are attached above to the lateral malleolus and below to the lateral surface of the calcaneus.

**INFERIOR PERONEAL RETINACULUM.** The inferior peroneal retinaculum (Fig. 6-79) is continuous with the fibers of the inferior extensor retinaculum above and is attached behind to the lateral surface of the calcaneus. Some of the fibers are attached to the peroneal trochlea and form a septum between the tendons of the peroneus longus and peroneus brevis.

### *Synovial Sheaths of the Tendons Around the Ankle*

All of the tendons that cross the ankle joint are enclosed for part of their length in synovial sheaths (Figs. 6-80; 6-81). These have an almost uniform length of about 8 cm each. On the anterior aspect of the ankle joint, the sheath for the tibialis anterior extends from the proximal margin of the superior extensor retinaculum to the interval between the diverging limbs of the inferior retinaculum. The common sheath for the extensor digitorum longus and peroneus tertius and the sheath for the extensor hallucis longus reach proximally to just above the level of the malleoli, the former being the higher. The sheath of the extensor hallucis longus is prolonged to the base of the first metatarsal bone, while that of the extensor digitorum longus reaches only to the level of the base of the fifth metatarsal.

On the *medial aspect of the ankle joint* (Fig. 6-81), the sheath for the tibialis posterior extends most proximally—to about 4 cm above the medial malleolus—while distally it ends just above the tuberosity of the navicular. The sheath for the flexor hallucis longus commences above at the level of the malleolus, while that for the flexor digitorum longus starts slightly higher. The former is continued distally to the base of the first metatarsal, but the latter stops opposite the medial cuneiform bone.

On the *lateral aspect of the ankle joint* (Fig. 6-80), a sheath that is single for the greater part of its extent encloses the tendons of the peroneus longus and brevis. It extends proximally 4 cm above the medial malleolus before it splits into separate

sheaths for the two tendons lateral to the calcaneus. Each sheath then continues distally for about another 4 cm.

## MUSCLES AND FASCIAE OF THE FOOT

The skin and superficial fascia on the dorsum of the foot are thin and loosely adherent. The underlying **deep fascia**, also a thin layer, is continuous above with the superior and inferior extensor retinacula. On both sides of the foot, it blends with the plantar aponeurosis, and anteriorly it invests the tendons on the dorsum of the foot.

### *Dorsal Muscle of the Foot*

**EXTENSOR DIGITORUM BREVIS.** The extensor digitorum brevis (Fig. 6-80) is a broad, thin muscle that arises from the superior (proximal) surface of the calcaneus, anterior and lateral to the calcaneal sulcus and distal to the groove for the peroneus brevis. Some of its fibers also arise from the lateral talocalcaneal ligament and from the common limb of the inferior extensor retinaculum. It passes obliquely across the dorsum of the foot and ends in four tendons. The most medial, which is the largest, crosses the dorsalis pedis artery and is inserted into the dorsal surface of the base of the proximal phalanx of the great toe. It is frequently described as a separate muscle, the **extensor hallucis brevis**. The other three are inserted into the lateral surfaces of the tendons of the extensor digitorum longus muscle of the second, third, and fourth toes.

**Action.** The extensor digitorum brevis extends the proximal phalanx of the great toe, and by its attachments to the tendons of the extensor digitorum longus, it extends the phalanges of the second, third, and fourth toes.

**Nerve.** The extensor digitorum brevis is supplied by a branch of the **deep peroneal nerve**, containing fibers from fifth lumbar and first sacral nerves.

**Variations.** Accessory slips of origin to the extensor digitorum brevis from the talus and navicular, or from the lateral cuneiform and third metatarsal bones, or from the cuboid bone have been observed. The tendons vary in number and position. They may be reduced to two, or one of them may be doubled, or an additional slip may pass to the little toe. A supernumerary slip ending on one of the metatarsophalangeal articulations or joining a dorsal interosseous muscle is not uncommon.

### Plantar Aponeurosis

The plantar aponeurosis is of great strength and consists of pearly white glistening fibers disposed, for the most part, longitudinally. It is divided into central, lateral, and medial portions.

The **central portion** is the thickest. It is narrow behind and attached to the medial process of the tuberosity of the calcaneus, proximal to the origin of the flexor digitorum brevis (Fig. 6-82). It becomes broader and thinner distally and divides near the heads of the metatarsal bones into five processes, one for each of the toes. Each of these processes separates opposite the metatarsophalangeal joint into two strata, superficial

and deep. The superficial stratum is attached to the skin of the transverse sulcus, which separates the toes from the sole. The deeper stratum divides into two slips and these embrace the sides of the flexor tendons of the toes, blending with the sheaths of the tendons and with the transverse metatarsal ligament, and forming a series of arches through which the tendons of the short and long flexors pass to the toes. At the intervals between the five processes, the digital vessels and nerves and the tendons of the lumbrical muscles become superficial. At the point of division of the aponeurosis, numerous transverse fasciculi add to the strength of the aponeurosis by binding the processes together, and connecting them with the integument. The central portion of the plantar aponeurosis is continuous with the lateral and medial portions. At these lines of junction, two strong vertical intermuscular septa, broader distally than proximally, are sent deeper into the foot. These separate the intermediate from the lateral and medial groups of plantar muscles. From these vertical septa are derived thinner transverse septa, which separate the various layers of muscles in this region. The deep surface of this aponeurosis gives origin proximally to some fibers of the flexor digitorum brevis. The lateral and medial portions of the plantar aponeurosis, which cover the sides of the sole of the foot, are thinner than the central portion.

The **lateral portion** lies superficial to the abductor digiti minimi muscle. It is thin distally and thick proximally, where it forms a strong band between the lateral process of the tuberosity of the calcaneus and the base of the fifth metatarsal bone. It is continuous medially with the central portion of the plantar aponeurosis, and laterally with the fascia on the dorsum of the foot.

The **medial portion** is thin and lies superficial to the abductor hallucis muscle. It is attached behind to the flexor retinaculum and is continuous medially, around the side of the foot, with the fascia on the foot dorsum and laterally with the central portion of the plantar aponeurosis.

### Plantar Muscles of the Foot

The muscles in the plantar region of the foot can be divided into three groups—medial, lateral, and intermediate, like those

FIG. 6-82. The first layer of plantar muscles. Right foot.

in the hand. The medial plantar muscles comprise the intrinsic muscles of the great toe and correspond to those of the thumb. The lateral plantar muscles consist of the intrinsic muscles of the small toe and correspond to those of the little finger. The intermediate plantar muscles, including the lumbricals, the interossei, the flexor digitorum brevis, and the quadratus plantae, are connected with the tendons intervening between the two former groups. In order to facilitate the description of these muscles, it is more convenient to divide them into four layers, in the sequence encountered during dissection.

#### FIRST LAYER

This is the most superficial of the plantar layers and consists of three muscles, all of which arise from the calcaneus. They lie deep to the plantar aponeurosis and are surrounded by their own fascial covering.

Abductor hallucis  
Flexor digitorum brevis  
Abductor digiti minimi

**ABDUCTOR HALLUCIS.** The abductor hallucis (Fig. 6-82) lies along the medial border of the foot, covering the entrance of the plantar vessels and nerves into the sole. It arises from the medial process of the tuberosity of the calcaneus, from the flexor retinaculum, from the plantar aponeurosis, and from the intermuscular septum between it and the flexor digitorum brevis. The fibers end in a tendon that is inserted, together with the medial tendon of the flexor hallucis brevis, into the medial side of the base of the proximal phalanx of the great toe.

**Action.** Although the **abductor hallucis** can abduct the great toe at the metatarsophalangeal joint, it probably acts more consistently as a flexor at that joint.

**Nerve.** The abductor hallucis is supplied by a branch of the **medial plantar nerve**, containing fibers from the fifth lumbar and first sacral nerves.

**FLEXOR DIGITORUM BREVIS.** The flexor digitorum brevis lies in the middle of the sole of the foot, immediately deep to the central part of the plantar aponeurosis, to which many of its fibers are firmly united (Fig. 6-82). Its deep surface is separated from the lateral plantar vessels and nerves by a thin

layer of fascia. It arises by a narrow tendon from the medial process of the tuberosity of the calcaneus, as well as from the central part of the plantar aponeurosis and from the intermuscular septa between it and the adjacent muscles. It passes distally and divides into four tendons, one for each of the four lesser toes. Opposite the bases of the proximal phalanges, each tendon divides into two slips through which passes the corresponding tendon of the flexor digitorum longus. The two portions of the tendon then reunite and form a grooved channel for the accompanying long flexor tendon. Finally, the tendon of the flexor digitorum brevis divides a second time and is inserted onto both sides of the middle phalanx. The mode of division of the tendons of the flexor digitorum brevis, and of their insertion into the phalanges, is comparable to that of the tendons of the flexor digitorum superficialis in the hand.

**Action.** The **flexor digitorum brevis** flexes the second phalanges of the four lateral toes.

**Nerve.** The flexor digitorum brevis is supplied by a branch of the **medial plantar nerve**, containing fibers from the fifth lumbar and first sacral nerves.

**Variations.** The tendon to the little toe is frequently absent (38%), or it may be replaced by a small fusiform muscle arising from the long flexor tendon (33%), or from the quadratus plantae.

#### FIBROUS SHEATHS OF THE FLEXOR TENDONS.

The terminal portions of the tendons of the long and short flexor muscles are contained in osseous-aponeurotic canals similar in their arrangement to those in the fingers. These canals are limited dorsally by the phalanges and on the plantar aspect by fibrous bands called **digital fibrous sheaths**, which arch across the tendons and are attached on both sides to the margins of the phalanges. Opposite the bodies of the proximal and middle phalanges, the **annular part** of the fibrous bands is strong, and the fibers are transverse. Opposite the joints, the **cruciate part** of the fibrous sheaths is much thinner and the fibers are directed obliquely. Each canal contains a synovial sheath, which is reflected around the contained tendons and is attached to the tendons by **vincula tendinum** similar to those in the digits of the hand.

**ABDUCTOR DIGITI MINIMI.** The abductor digiti minimi (Fig. 6-82) lies along the lateral border of the foot, its medial margin being

related to the lateral plantar vessels and nerves. It arises, by a broad origin, from the lateral process and distal part of the medial process of the tuberosity of the calcaneus, as well as from the intervening plantar surface of the bone. It also arises from the plantar aponeurosis and from the intermuscular septum between it and the flexor digitorum brevis. Its tendon, after gliding over a smooth facet on the plantar surface of the base of the fifth metatarsal bone, is inserted, with the flexor digiti minimi brevis, into the lateral aspect of the base of the proximal phalanx of the little toe.

**Action.** The **abductor digiti minimi** abducts and helps to flex the small toe at the metatarso-phalangeal joint.

**Nerve.** The abductor digiti minimi is supplied by a branch of the **lateral plantar nerve**, containing fibers from the second and third sacral nerves.

**Variations.** Usually some fibers of this muscle insert onto the tuberosity at the base of the fifth metatarsal. At times these fibers actually constitute a separate muscle, the **abductor ossis metatarsi quinti**, with fibers arising on the lateral process of the tuberosity of the calcaneus and inserting onto the tuberosity of the fifth metatarsal bone in common with or beneath the outer margin of the plantar fascia.

## SECOND LAYER

The intrinsic muscles of the second layer are all attached to the tendons of the flexor digitorum longus as that muscle courses through the sole of the foot on its way to the digits. The muscles of this layer are:

Quadratus plantae  
Lumbricales

**QUADRATUS PLANTAE.** The quadratus plantae (Fig. 6-83), also known as the flexor accessorius, alters the posteromedial pull of the tendon of the flexor digitorum longus into an almost straight posteriorly oriented pull. Between it and the muscles of the first layer are found the lateral plantar vessels and nerve. It arises by two heads, which are separated from each other by the long plantar ligament. The larger, muscular **medial head** arises from the medial concave surface of the calcaneus, below the groove that lodges the tendon of the flexor hallucis longus. The **lateral head**, which is flat and tendinous, arises from the lateral border of the calcaneus, distal to the lateral process of

Fig. 6-83. The second layer of plantar muscles. Right foot.

its tuberosity, and from the long plantar ligament. The two portions join at an acute angle and end in a flattened muscular band, which is inserted deep to and along the lateral margin of the tendon of the flexor digitorum longus near the middle of the plantar region. The deeper part of the quadratus plantae usually sends slips to those tendons of the flexor digitorum longus that pass to the second, third, and fourth toes.

**Action.** The **quadratus plantae** helps the flexor digitorum longus to flex the terminal phalanges of the four small toes.

**Nerve.** The quadratus plantae is supplied by a branch of the **lateral plantar nerve**, containing fibers from the second and third sacral nerves.

**Variations.** The lateral head or sometimes the

entire muscle is absent. The muscle varies with respect to the number of digital tendons receiving muscular slips. Occasionally, tendons to only two toes receive muscle fibers; sometimes those to the fourth are absent, and in many cases, fibers are sent to the fifth.

**THE LUMBRICALS.** The lumbricals are four small muscles, accessory to the tendons of the flexor digitorum longus, numbered from the medial side of the foot (Fig. 6-83). They arise from these tendons, as far back as their angles of division. Each lumbrical springs from two tendons except the first, which arises along the medial surface of the first tendon. The muscles end in tendons, which pass distally along the medial sides of the four lesser toes and are inserted into the expansions of the tendons of the extensor digitorum longus on the dorsal surfaces of the proximal phalanges.

**Action.** The lumbricals in the foot, similar to those in the hand, flex the proximal phalanges at the metatarsophalangeal joints and extend the two distal phalanges at the interphalangeal joints of the four lateral toes.

**Nerves.** The first lumbrical is supplied by a branch of the **medial plantar nerve**, containing fibers from the fifth lumbar and first sacral nerves. The other three lumbricals receive branches of the **lateral plantar nerve**, containing fibers from the second and third sacral nerves.

**Variations.** Absence of one or more lumbrical muscles has been noted, and doubling of the third or fourth has been reported. At times they may be inserted partly or wholly onto the bone of the first phalanges instead of the dorsal expansions.

### THIRD LAYER

Two short flexors, one for the large toe and one for the little toe, and the adductor of the large toe comprise the muscles of the third layer. They are:

Flexor hallucis brevis  
Adductor hallucis  
Flexor digiti minimi brevis

**FLEXOR HALLUCIS BREVIS.** Throughout most of its extent, the flexor hallucis brevis lies adjacent to the plantar surface of the first metatarsal bone (Fig. 6-84). It arises by a pointed tendinous process from the medial part of the plantar surface of the cuboid bone, from the contiguous portion of the lateral cuneiform, and from the prolongation of the tendon of the tibialis posterior, which is

Fig. 6-84. The third layer of plantar muscles. Right foot.

attached to that bone. It divides distally into medial and lateral parts, which are inserted into the medial and lateral aspects of the base of the proximal phalanx of the large toe, a sesamoid bone being present in each tendon at its insertion. The **medial part** is blended with the abductor hallucis of the first layer just before its insertion, while the **lateral part** inserts near the tendon of the adductor hallucis. The tendon of the flexor hallucis longus lies in a groove between the two parts.

**Action.** The flexor hallucis brevis flexes the proximal phalanx of the large toe at the metatarsophalangeal joint.

**Nerve.** The flexor hallucis brevis is supplied by a

branch of the **medial plantar nerve**, containing fibers from the fifth lumbar and first sacral nerves.

**Variations.** The origin of the flexor hallucis brevis may vary. It often receives fibers from the calcaneus or long plantar ligament, and the attachment to the cuboid may be absent. An additional slip may insert onto the proximal phalanx of the second toe.

**ADDUCTOR HALLUCIS.** The adductor hallucis consists of oblique and transverse heads (Fig. 6-84). The **oblique head** is a large, thick, fleshy mass, which occupies an otherwise hollow space superficial to the first, second, third, and fourth metatarsal bones. It arises from the bases of the second, third, and fourth metatarsal bones, and from the sheath of the tendon of the peroneus longus. Crossing obliquely to the medial side of the foot, it is inserted, together with the lateral portion of the flexor hallucis brevis, into the lateral aspect of the base of the proximal phalanx of the large toe. The **transverse head** is a narrow, flat fasciculus that arises from the plantar metatarsophalangeal ligaments of the third, fourth, and fifth toes (sometimes only from the third and fourth) and from the transverse metatarsal ligaments of these same digits. Coursing medially, its fibers are inserted into the lateral aspect of the base of the proximal phalanx of the large toe, its fibers blending with the tendon of insertion of the oblique head.

**Action.** The adductor hallucis adducts the large toe, drawing it toward the longitudinal axis of the foot. It also flexes the proximal phalanx of the large toe at the metatarsophalangeal joint and helps to maintain the transverse metatarsal arch.

**Nerve.** The adductor hallucis is supplied by a branch of the **lateral plantar nerve**, containing fibers from the second and third sacral nerves.

**Variations.** A small slip of the muscle may insert onto the base of the proximal phalanx of the second toe. At times a portion of the muscle may insert onto the first metatarsal bone, constituting an **opponens hallucis** muscle.

**FLEXOR DIGITI MINIMI BREVIS.** The short flexor of the little toe lies superficial to the fifth metatarsal bone and resembles one of the interossei (Fig. 6-84). It arises from the base of the fifth metatarsal bone and from the sheath of the peroneus longus. Its tendon is inserted into the lateral aspect of the base of the proximal phalanx of the fifth toe. Occasionally a few of the deeper fibers are in-

serted into the lateral part of the distal half of the fifth metatarsal bone, being described by some authors as a distinct muscle, the **opponens digiti minimi**.

**Action.** The flexor digiti minimi brevis flexes the proximal phalanx of the small toe at the metatarsophalangeal joint.

**Nerve.** The flexor digiti minimi brevis is supplied by a branch of the **lateral plantar nerve**, containing fibers from the second and third sacral nerves.

#### FOURTH LAYER

The fourth layer of muscles on the plantar aspect of the foot consists of the **interossei**. These are similar to the interossei in the hand, except that their action is considered relative to the midline of the second digit, through which the longitudinal axis of the foot courses, in contrast to the midline of the third digit, as is the case in the hand. There are seven interossei in the foot and they are arranged in two groups:

- Dorsal interossei
- Plantar interossei

**DORSAL INTEROSSEI.** The dorsal interossei (Fig. 6-85), situated between the metatarsal bones, are four bipennate muscles, each arising by two heads from the adjacent sides of the metatarsal bones between which it is

Fig. 6-85. The dorsal interossei. Left foot, dorsal view.

**FIG. 6-86.** The plantar interossei. Left foot, plantar view.

placed. Their tendons are inserted into the bases of the proximal phalanges and into the dorsal digital aponeuroses of the tendons of the extensor digitorum longus. The first is inserted into the medial side of the second toe, while the other three are inserted into the lateral aspects of the second, third, and fourth toes. In the angular interval left between the heads of each of the three lateral dorsal interosseous muscles, one of the perforating arteries passes to the dorsum of the foot. Through the space between the two heads of the first muscle, the deep plantar branch of the dorsalis pedis artery enters the sole of the foot.

**Action.** The dorsal interossei abduct the toes from the longitudinal axis, which extends through the second toe. They also flex the proximal phalanx and extend the distal phalanges.

**Nerves.** The dorsal interossei are supplied by twigs from the **lateral plantar nerve**, containing fibers from the second and third sacral nerves. The fourth dorsal interosseous receives nerve fibers from the superficial branch, while the other three receive their innervation from the deep branch of the lateral plantar nerve.

**PLANTAR INTEROSSEI.** The plantar interossei, which are three in number, lie along the plantar surface of the metatarsal bones,

rather than between them. Each is connected with but one metatarsal bone. They arise from the bases and medial sides of the bodies of the third, fourth, and fifth metatarsal bones; they are inserted into the medial sides of the bases of the proximal phalanges of the same toes and into the dorsal digital aponeuroses of the tendons of the extensor digitorum longus.

**Action.** The plantar interossei adduct the third, fourth, and fifth toes toward the axis of the second toe. They also flex the proximal and extend the distal phalanges.

**Nerve.** The plantar interossei are supplied by branches of the **lateral plantar nerve** that contain fibers from the second and third sacral nerves. The third (most lateral) interosseous muscle is supplied by the superficial branch of the lateral plantar nerve, while the other two are supplied by the deep branch.

**Group Actions of Muscles at the Metatarsophalangeal Joints of the Toes.** *Flexion* of the toes at these joints is performed by the flexor digitorum longus, the quadratus plantae, the flexor digitorum brevis, the flexor hallucis longus and brevis, the flexor digiti minimi brevis, as well as the lumbricals and interossei. *Extension* at the metatarsophalangeal joint is performed by the extensors digitorum longus and brevis and the extensor hallucis longus. *Abduction* of the toes results from the action of the dorsal interossei, the abductor hallucis, and the abductor digiti minimi. *Adduction* of the toes is performed by the plantar interossei and the abductor hallucis.

**Group Actions of Muscles at the Interphalangeal Joints of the Toes.** *Flexion* of the toes at the interphalangeal joints occurs through the action of the flexor digitorum longus with the assistance of the quadratus plantae. The flexor digitorum brevis flexes the interphalangeal joints between the middle and proximal phalanges, while the flexor hallucis longus flexes the interphalangeal joint of the large toe. *Extension* of the interphalangeal joints is performed by the extensor digitorum longus, the lumbricals, and the interossei, as well as the extensor digitorum brevis and extensor hallucis longus.

## Structure of Skeletal Muscle

The contractile property of muscle tissue allows for movement of limbs and other body parts. Although the fundamental units of muscle tissue are called **muscle fibers**, these elements are in fact elongated cells containing nuclei and cytoplasm. There are two general types of muscle, smooth and striated. **Smooth muscle** is generally found in the walls of viscera and is under the neu-

ral control of motor fibers in the visceral nervous system (the autonomic nervous system). **Striated muscle**, however, is further subdivided into **cardiac striated muscle**, which is found in the walls of the heart, and **skeletal striated muscle**. The latter is connected to the bony skeleton and forms the bulk of the flesh in the body; it is under voluntary neural control by way of the somatic motor nerve fibers in the cranial and spinal nerves. All the muscles described in this chapter are formed of skeletal striated muscle. Because the chapter on the heart will describe cardiac striated muscle, and chapters on the viscera will elaborate the structure of smooth muscle, this discussion will be limited to the general organization, cellular features, and ultrastructural characteristics of skeletal striated muscle.

**GENERAL ORGANIZATION OF SKELETAL MUSCLE.** Skeletal muscle is designed principally for mobility, serving to enable an organism to react appropriately to environmental conditions. Yet, skeletal muscles benefit the body in more ways than only the production of movement. They also produce body heat, and to function effectively they must limit movement, as well as counteract the force of gravity in order to maintain posture. Most skeletal muscles are connected to bones, cartilages, or ligaments, usually through the intervention of tendons or aponeuroses. These

tendinous attachments to bone may be long (insertion of semitendinosus or origin of long head of biceps brachii), or the muscle fibers may attach quite directly to the bone (origins of lateral and medial heads of triceps brachii). Muscles may also attach to the skin (facial muscles), to a mucous membrane (certain tongue muscles), or to a fibrous plate (extraocular muscles), or they may form circular bands (sphincter muscles).

The long, cylindrical, striated skeletal muscle fibers (Fig. 6-87) are arranged, more or less, in a parallel manner to form bundles or **fascicles**. Between the individual muscle fibers ramifies a delicate network of connective tissue called the **endomysium** (Fig. 6-87). Each bundle or fascicle is surrounded by a more distinct, but still thin, layer of collagenous and elastic connective tissue, the **perimysium**, which binds the fascicles into larger groups and forms the fibrous septa throughout a muscle (Fig. 6-87). Investing the entire muscle is the connective tissue **epimysium**. This latter covering may be well developed, or it may be quite delicate, as it is when a muscle glides freely beneath a strong fascial sheet. At times the epimysium may lose its identity and even become fused with the surrounding fascial layer, especially if the adjacent fascia is used by some of the muscle fibers for their attachment. Such an elaborate meshwork of stromal connective

**Fig. 6-87.** Striated muscle. Muscles of the tongue. 320  $\times$ . Stain: hematoxylin-eosin. (From di Fiore, *Atlas of Human Histology*, 5th Ed., Lea & Febiger, 1981.)

tissue elements allows for a more independent action of the individual fascicles and muscle fiber groups.

In principle, the ends of muscle fibers attach in a similar manner whether the fasciculi end in a tendon or are connected directly to bones or cartilage. Each muscle fiber has a distinct termination, which is rounded, conical, or truncated, and is covered by the muscle fiber membrane. The collagen fibrillae of the endomysium become thickened and closely adherent to the end of the fiber as they pass over it (Fig. 6-88). The collagen fibers then course beyond the muscle fiber into the tendon, where they become the actual substance of the tendon (Goss, 1944). In muscles that appear to attach directly to bones, cartilages, or other structures, the fibers of the endomysium become continuous with the periosteum or other fibrous layers in the same manner as with a tendon. When the muscle fibers terminate within a fasciculus, as in long muscles, the ends of the fibers may be either blunt or long and tapering, and they are secured in place by the merging of their terminal endomysium with the endomysium of neighboring fibers. These findings have been confirmed by electron microscopy (Mackey et al., 1969).

Skeletal muscle is well supplied with both vessels and nerves. Arterial and venous vessels course through the perimysium, eventually dividing into fine capillaries which ramify among the individual muscle fibers, anastomosing freely and forming a rich bed for the exchange of nutrients and metabo-

lites. Accompanying the vessels in the perimysium are branches of larger nerve trunks, which together with the vessels frequently form a neurovascular network in the connective tissue septa between the fascicles of a muscle. Finer branching of the nerve trunks eventually results in both the motor and sensory innervation of the individual skeletal muscle fibers. A single alpha motor nerve fiber may supply anywhere from three to over two thousand skeletal muscle fibers. In muscles serving to produce fine movements under discriminating voluntary control, such as the extraocular muscles in the orbit, each nerve fiber innervates a small number of muscle fibers. In contrast, muscles producing gross movements have many hundreds of muscle fibers supplied by a single nerve fiber. A single motor nerve fiber (**alpha efferent**) and all the muscle fibers that it innervates constitute a functional subdivision of muscle and collectively are called the **motor unit**. Thus, when a nerve impulse travels along a motor nerve fiber that it supplies, all of the muscle fibers in the motor unit contract together. Muscle is also supplied with sensory fibers, most of which course from receptor sites in neuromuscular spindles and Golgi<sup>1</sup> tendon organs.

**Neuromuscular spindles** are composed of three to fewer than twenty striated muscle fibers surrounded by a thick connective tissue capsule. These intracapsular muscle fi-

<sup>1</sup>Camillo Golgi (1843–1926): An Italian anatomist (Pavia and Siena).

**FIG. 6-88.** Attachment of a muscle fiber from the flexor digitorum superficialis of a monkey. Reticular connective tissue fibrils are blackened with Masson's silver stain. 900  $\times$ . (From Goss, 1944.)

bers are called **intrafusal** to differentiate them from the **extrafusal** muscle fibers in the remainder of the muscle (Fig. 6-89). Surrounded by afferent nerve fibers, the intrafusal fibers of muscle spindles receive motor innervation by a special group of nerve fibers called the **gamma efferents**. Muscle spindles serve as receptors in many somatic muscles and are capable of responding to a stretching of the entire muscle, or a part of it, thereby initiating a sensory discharge in their afferent fibers. This feedback information to the central nervous system is importantly involved in muscle control and the maintenance of muscle tone.

#### CELLULAR FEATURES OF SKELETAL MUSCLE.

The principal parenchymal unit in skeletal muscle is the striated skeletal muscle cell. These may be large, exceedingly long cells, like those in the sartorius muscle, extending many centimeters in length and measuring from 10 to 100 microns in width, or they may be only a few millimeters in length and extremely slender. If teased apart, skeletal muscle cells can be within the limit of visibility of the naked eye.

Each striated muscle cell is multinucleated, the numbers of nuclei being proportional to the volume of the cell. The nuclei are flat, elongated discs with their long axis oriented in the direction of the muscle fiber. Although they are numerous and irregularly

placed along the muscle fiber, they are located close to the inner surface of the outer cell membrane or **sarcolemma** (Fig. 6-90). In special preparations, the mitochondria and the Golgi apparatus can be demonstrated adjacent to the poles of each skeletal muscle cell nucleus. In addition to the nuclei of the skeletal muscle cell, striated muscle tissue contains nuclei of fibroblasts, as delicate wisps of connective tissue forming the **endomysium** are interposed between the muscle cells.

Within the sarcoplasm (cytoplasm) of skeletal muscle cells are found many longitudinally oriented parallel units called **myofibrils**. These are visible with the light microscope and measure less than one micron to about two or three microns in diameter. When muscle fibers are cut in cross section, the myofibrils appear as clusters of fine dots that occupy nearly all of the intracellular volume (Fig. 6-90). Between the myofibrils, however, are small amounts of sarcoplasm that slightly separate them from each other. In longitudinal sections, the most remarkable characteristic of skeletal muscle cells is their **cross striations** (Fig. 6-91). The cross striated appearance is due to the fact that the myofibrils consist of alternating dark (**A band**) and light (**I band**) staining segments. When observed with the polarizing microscope, the bands that appear dark with the

**Fig. 6-89.** Cross section of part of a lumbrical muscle from a human hand, showing extrafusal and intrafusal muscle fibers, endomysium, blood capillaries, and a muscle spindle. Approximately 400  $\times$ . (From Rauber-Kopsch, *Lehrbuch u. Atlas d. Anatomie d. Menschen*, 19th Ed., Vol. I, Georg Thieme Verlag, 1955.)

**Fig. 6-90.** Photomicrograph of striated muscle fibers cut in cross section. Note that within each muscle fiber are many myofibrils and that the nuclei are placed near the surface of the fiber membrane. (From Ham, *Histology*, 7th Ed., J. B. Lippincott, 1974.)

ordinary light microscope are doubly refractile (birefringent) or **anisotropic** (hence called A bands). Contrastingly, the light staining bands of customary histologic preparations appear **isotropic** with polarizing light (hence called I bands).

The cross striations of adjacent myofibrils within a skeletal muscle cell observed in longitudinal section are not exactly aligned, and the intervening sarcoplasm does not show striations. They are, however, evenly registered and thereby give the muscle fiber striations the appearance of extending across the entire fiber. Well-fixed light microscopic preparations of longitudinally oriented skeletal muscle cells reveal a dark transverse line that bisects each lightly stained I band. This line, called the **Z line** (*zwichenscheibe*), may be conceived of as a septum across the myofibril and is designated as the limits of a **sarcomere**. The sarcomere is the repeating structural unit of a myofibril as well as its functional unit of

contraction. Thus, between two Z lines, the sarcomere includes one A band, plus one half of an I band on each of its ends (Fig. 6-92).

There appears to be morphological correlation to the speed of contraction of muscle fibers. Two main types of fibers have been identified: small-diameter **red fibers**, which are rich in mitochondria and myoglobin and are surrounded by more blood capillaries, and large-diameter **white fibers**, which contain little myoglobin and few mitochondria (Gauthier, 1970). Frequently, muscles consist of a mixture of the fiber types, but in certain muscles one fiber type predominates over the other. The duration of contraction of red muscle fibers may last ten times that of white muscle fibers. The soleus muscle, which must function for extended periods of time as an antigravity muscle, principally consists of red muscle fibers. It contracts slowly, but the duration of its contraction is quite long (100 msec). In contrast, extraocular muscles, which rapidly fixate the eyeballs, consist of white fibers that allow muscle contractions to be rapid but of short duration (10 msec).

**ULTRASTRUCTURAL FEATURES OF SKELETAL MUSCLE.** Although the A bands, I bands, and Z lines can quite readily be observed with ordinary microscopy, the electron microscope has significantly contributed to an understanding of skeletal muscle. First of all, the dark staining A band is crossed by a lighter band called the **H zone** (Hensen's zone<sup>1</sup>). In turn, the lighter H zone is bisected by a slightly darker M line (Fig. 6-92). The individual myofibrils within a skeletal muscle cell are themselves composed of longitudinally oriented **myofilaments**. Two types of myofilaments have been identified according to their size and chemical composition. The thicker ones, between 100 Å to 150 Å in diameter, are confined to the A band and are **myosin myofilaments**, about 1.5 microns long. The thinner myofilaments are between 50 Å and 80 Å in diameter and attach at their middle to the Z line, from which they extend for about one micron in either longitudinal direction. Chemically, they are the **actin myofilaments**, and they form the I bands. Additionally, these thin actin filaments extend from the I bands into the adjacent A

<sup>1</sup>Victor Hensen (1835-1924): A German anatomist and physiologist (Kiel).

**Fig. 6-91.** Photomicrograph of longitudinally sectioned skeletal muscle fibers. Arrow points to a nucleus just beneath the sarcolemma of one of the muscle fibers. Note the cross striations. The wide, dark striations are the A bands; the light striations are the I bands. Each I band is bisected by a narrow dark Z line. 2000  $\times$ . (Modified from Copenhagen, Kelly, and Wood, *Bailey's Textbook of Histology*, 17th Ed., Williams and Wilkins, 1978.)

bands, interdigitating with the thicker myosin filaments in a regular manner (Fig. 6-93). Each thick myosin filament in the A band is surrounded by six thin actin filaments, spaced evenly and hexagonally around the myosin filament (Fig. 6-94).

Ultrastructural studies have shown that the thin actin filaments of *relaxed* muscle fibers extend into the A bands from each side, but they do not meet at the center. The central part of the A band in relaxed muscle, into which the actin filaments do not invade, is the lighter H zone. When muscle fibers contract, the thin actin filaments slide further into the A band, meeting in the center or even sliding past each other, thereby reducing the size of the H zone or eliminating it altogether (Fig. 6-95). Because the former H

zone contains both types of filaments in a contracted fiber, it becomes as dense as the rest of the A band. The Z lines are simultaneously pulled closer to the A bands, and therefore the I bands also become reduced in size. Although the length of the sarcomere is reduced, contraction involves not a reduction in the size of either the actin or myosin protein components, but an attraction of these two elements for each other, so that their surface areas can achieve the maximum contact for the formation of the **actomyosin complex**. This process requires the energy supplied by the breakdown of ATP (adenosintriophosphate), found in the mitochondria, to ADP (adenosindiphosphate).

Other important ultrastructural features of skeletal muscle cells are beginning to elu-

**Fig. 6-92.** Electron micrograph of five longitudinally oriented myofibrils in relaxed skeletal muscle. Observe that the limit of a sarcomere is defined as a region of a myofibril between two Z lines. This includes an A band capped at each end by one-half of an I band. (From Bloom and Fawcett, *A Textbook of Histology*, 10th Ed., W. B. Saunders Co., 1975.)

**Fig. 6-93.** Diagrammatic representation of the structure of striated muscle showing the overlapping arrays of the thinner, actin- and thicker myosin-containing filaments. Lower diagrams show cross-sectional patterns of the filaments through the A and H bands. (From H. E. Huxley, 1969. *Science*, 164: 1356. Copyright 1969 by the American Association for the Advancement of Science.)

**Fig. 6-94.** Electron micrograph of frog sartorius myofibrils showing A bands cut in cross section. Note that the thick myosin filaments within the myofibril are each surrounded by six thin actin filaments. 150,000  $\times$ . (Modified from H. E. Huxley, 1968.)

**Fig. 6-95.** This diagram shows the changes that occur in a sarcomere with muscle contraction. During contraction (low part), the thin actin filaments slide toward the center of the A band. This diminishes the width of the I bands and the H band seen in relaxed muscle (upper part). (From Windle, *Textbook of Histology*, 4th Ed., McGraw-Hill, 1969. Used with permission of McGraw-Hill Book Company.)

cidate how the contraction of myofibrils is initiated by arriving nerve impulses to the surface membrane or sarcolemma of the muscle cell. Myofibrils are encased longitudinally by a parallel array of interconnected membranous tubules and cisternae that composes the **sarcoplasmic reticulum** (Figs. 6-96; 6-97). Extending along both the A band and the I band, the sarcoplasmic reticulum fuses to form a cisterna at the H zone. Near both ends of the sarcomere at the Z lines, the tubules expand and coalesce to form terminal cisternae. Each terminal cisterna interfaces another, located on the opposite side of the Z line. At this site (in amphibian muscle) or at the junction of the A band and I bands (in mammalian muscle), the terminal cisternae of the sarcoplasmic reticulum become associated with a transverse tubular system that courses along the Z line called the **T system**. The T tubule and the two terminal cisternae are collectively referred to as the **triad** (Figs. 6-96; 6-97). It has been shown that the T tubule, which passes all the way through the muscle fiber from one side of the sarcolemma to the

other, opens extracellularly. It is in contact with the exterior of the cell and contains extracellular fluid (Fig. 6-98).

With the T tubules in continuity with the extracellular space and the sarcoplasmic reticulum intimately associated with the intracellular contractile components of the muscle fiber, a morphological system exists that can communicate surface events occurring on the sarcolemma to the contractile substructure in the interior of the myofibril. It has been proposed that the contractile wave of depolarization initiated at the myoneural junction spreads not only along the skeletal muscle surface, but also through the T tubule system. In some manner, this excitation is transmitted across the common membranous wall shared by the T tubule and the terminal cisternae of the sarcoplasmic reticulum, which contains calcium ions. The release of calcium within the sarcoplasmic reticulum probably initiates contraction, after which calcium becomes bound once again, perhaps by a relaxation factor, leading to relaxation of the myofibrils.

**FIG. 6-96.** This drawing depicts the relationship between the myofibrils (four are shown) of a muscle fiber, the associated sarcoplasmic reticulum (SR), and the T system (TS). The sarcoplasmic reticulum expands into terminal cisterns (SR') at the I bands, and forms at the Z lines a triad (see three arrows) with the T tubule. (From Porter and Bonneville, *Fine Structure of Cells and Tissues*, 4th Ed., Lea & Febiger, 1973.)

**FIG. 6-97.** Electron micrograph of the sarcoplasmic reticulum and T tubules of a goldfish skeletal muscle myofibril (78,300  $\times$ ). T: T tubules; Z: Z lines. Note the fenestrations (f) or pores in the sarcoplasmic reticulum at the H zone of the sarcomere. (From Uehara, Campbell, and Burnstock, *Muscle and Its Innervation*, Edward Arnold Publishers, Ltd., 1976.)

**FIG. 6-98.** Transverse section of a skeletal muscle fiber cutting across the Z line (Z) and showing the T tubules (T). The arrow indicates that the T tubule is in direct continuity with the external environment. Where the section cuts at the level of the I band, the terminal sacs of the sarcoplasmic reticulum (SR) can be seen. 38,500  $\times$ . (From Franzini-Armstrong and Porter, *J. Cell Biol.*, 1964.)

## The Heart

The **heart** is the central organ of the blood circulatory system. By its rhythmic contraction, this dynamic muscular structure pumps the blood through a system of **arteries** to all parts of the body. Blood flows in a continuous circulation, delivering oxygen and nutrients to all organs, including the heart itself. This is accomplished through an enormous ramification of the arteries into minute vessels called **arterioles**, which in turn form a network of **capillaries** that are microscopic in size and have very thin walls. Allowing an exchange of substances with the tissues, the capillaries collect as **venules**, which then drain into larger **veins** that progressively increase in diameter and eventually return blood to the heart.

The human heart is a four-chambered organ consisting of two **ventricles** and two **atria**. The powerful pumping portions of the heart are the right and left ventricles, which are separated by the muscular **interventricular septum**. The ventricles have thick walls and are made to function efficiently by being quickly and forcibly filled with blood by contraction of the right and left atria. As blood is returned to the heart through the **superior** and **inferior venae cavae**, it enters the **right atrium** and is then forced into the **right ventricle**. From here it is pumped through the **pulmonary arteries** and into the

capillaries of the lungs, where it is refreshed as carbon dioxide is removed and oxygen absorbed. Blood is returned by the **pulmonary veins** to the **left atrium**, which forces it into the **left ventricle**. The left ventricle propels oxygenated blood through the aorta and systemic arteries to the capillaries, and then back to the heart again through the venous system. The right side of the heart, the pulmonary arteries, the capillary system in the lungs, and the pulmonary veins constitute the **lesser or pulmonary circulation**. The left side of the heart, the aorta, the ramifying arteries to all the organs (except the lungs), and the returning veins (except the pulmonary veins) constitute the **systemic circulation** (Fig. 7-1).

Although the systemic circulation to and from most organs characteristically involves only one set of capillaries within the various tissues, an exception is found in the vessels of the abdominal organs. The blood supplied to the spleen, pancreas, stomach, and intestines by the systemic arteries collects into the large **portal vein**, which enters the liver and ramifies within it. As the blood passes through the capillary-like **hepatic sinusoids**, it exchanges nutrient materials with the liver cells, and is then collected into the hepatic veins (Fig. 7-1). These drain into the large inferior vena cava, which is transporting systemic venous blood, just before that vessel opens into the right atrium. This diversion of blood by the way of the portal vein from certain abdominal organs, through the liver and back into the inferior vena cava, constitutes the **portal circulation**.

The field of study of the vascular system is called **angiology**. It includes the study of blood vessels as well as vessels constituting the lymphatic system. Although the lymphatic system drains into the veins, making the two systems interdependent, there are sufficient differences morphologically and functionally to make their separate treatment advisable. For convenience of description, the field of angiology will be treated under four headings: the heart, the arteries, the veins, and the lymphatic system. These constitute the next four chapters.

### Development of the Heart

**FORMATION OF THE HEART TUBE.** The first primordium of the **vascular system** can be recognized soon after the initial appearance

**Fig. 7-1.** Schematic diagram of the blood vascular and lymphatic systems. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, 10th Ed., Vol 2, Urban & Schwarzenberg, 1975.)

of the **coelom** or body cavity within the embryo. This occurs on about the nineteenth or twentieth prenatal day, at a time when the mesoderm has been formed by the primitive streak, but before it has been organized into the primitive segments or somites. This first coelom is a U-shaped cavity encircling the cephalic end of the neural folds (Fig. 7-2). It is the primordium of the **pericardial cavity**. Its outer layer, the **somatic mesoderm**, will become the parietal pericardium; its inner layer, the **splanchnic mesoderm**, will develop into the myocardium and epicardium. Scattered cells of

mesodermal origin, called **mesenchyme**, migrate between the compact laminae of the splanchnic mesoderm and the entoderm. This mesenchyme proliferates rapidly and forms strands and sheets, which are the primordium of the **endocardium**.

The earliest stages of development of the human heart are imperfectly known because of the scarcity of available human embryos of this age. It is helpful, however, that the early development of the heart in lower mammalian embryos, such as the rat, is sufficiently similar to that seen in man to permit the use of timed specimens in these animals (Figs. 7-3 to 7-6) to elucidate the period between the human first somite stage (Fig. 7-2) and that of the human eight-somite stage (Fig. 7-7). It is convenient to use the number of somites as an index of the early stages of development because they can be counted accurately and they retain a relatively stable growth relationship to the rest of the embryo.

By the time the embryo has acquired its **first three somites** or primitive body segments and before the neural folds have closed to form the neural tube, the **endocardial mesenchyme** has spread in a thin sheet across the midline in the cranial portion of the embryo (Fig. 7-3). It also extends downward on each side of the still shallow foregut invagination, and a lumen has begun to form

**Fig. 7-2.** Human embryo with first somite forming, 1.5 mm in length. Dorsal view with amnion removed and ectoderm and mesoderm cut away to show pericardial cavity. (Redrawn from Davis, 1927.)

**FIG. 7-3.** Rat embryo with 3 somites. A, Ventral view with entoderm removed. Lumen of heart and vessels is incomplete. B, Median sagittal section of same embryo. Drawings of wax reconstruction made at  $400\times$  magnification. (From Goss, 1952.)

in these lateral extensions. The splanchnic mesoderm becomes thickened where it is in contact with the endocardium and is thus identifiable as the **primordium of the myocardium**. The myocardial layer is also deeply grooved along the lateral endocardial tubes. Thus, the two lateral endocardial tubes with their partial cloak of myocardium constitute the **primitive lateral hearts**, where the first contractions occur. The site of the future atrioventricular junction is marked by a constriction of the lumen of the lateral tube slightly caudal to the level of the foregut portal.

The median sheet of mesenchyme is quickly differentiated into endocardium by having the lumen extend into it from

the lateral tubes. At the same time, the sheet appears to pull in its outlying parts, resulting in a sac rather than a tube, which, with its adjacent myocardial mesoderm, constitutes the **primitive ventricle**. As the endocardial sac expands, it sinks deep into a pocket in the mesoderm. The pericardial cavity enlarges to accommodate this growth and in a **four-somite embryo** the entire cardiac complex bulges ventrally at the foregut portal (Fig. 7-4).

Until this time the myocardium has been entirely dorsal to the endocardium. The rapid expansion of the pericardial cavity in a ventral direction allows the myocardium to protrude ventrally over the endocardial sac, until, in a **five-somite**

**FIG. 7-4.** Rat embryo with 4 somites. A, Ventral view with entoderm removed. Compare endocardium with that in Figure 7-3. B, Median sagittal section of same embryo. (From Goss, 1952.)

**FIG. 7-5.** Rat embryo with 5 somites. A, Ventral view with entoderm removed. Ventral part of pericardium cut away to show myocardium. Dotted line indicates extent of endocardium inside ventricle. B, Median sagittal section of same embryo. Compare with Figures 7-3 and 7-4. (From Goss, 1952.)

**embryo**, the heart lies in a plane at right angles to the axis of the embryo with the arterial end more dorsally placed and the venous end more ventrally placed (Fig. 7-5).

By a continued rapid growth, the ventricular myocardium extends over the entire ventral surface of the endocardium (Fig. 7-6). In a **six-somite embryo**, it encloses the endocardium except for a narrow interval along the midline dorsally. This change allows the heart to assume a more tubular shape with cranial and caudal extremities. The opening of the aortic sac is always dorsal rather than cranial to the heart and the whole tube maintains a curvature with ventral convexity. The result is the marked ventral protrusion of the cardiac complex which is characteris-

tic of early mammalian embryos. When the embryo has acquired **seven somites**, the myocardium completely surrounds the endocardium. The middle portion of the tubular ventricle becomes free and only the ends are attached: the *arterial end* by its continuity with the aortic sac and first aortic arches, and the *venous end* by the atria and vitelline veins (Figs. 7-7; 7-9,A and B).

**DEVELOPMENT OF THE CARDIAC LOOP.** The length of the tubular heart increases much more rapidly than the longitudinal extent of the pericardium. The heart tube therefore continues to bend, this time in a loop with convexity to the right, called the **bulboventricular loop** (Figs. 7-7; 7-9,C). The resulting groove on the left side is called the **bulboventricular sulcus** and establishes a

**FIG. 7-6.** Rat embryo with 6 somites. A, Ventral view with entoderm removed. Ventral part of pericardium and myocardium also removed to show endocardium. B, Median sagittal section of same embryo. (From Goss, 1952.)

subdivision of the tube into the **bulbus cordis** (or conus) and the **primitive ventricle** (Figs. 7-8; 7-9,D). The ventricular portion increases rapidly in all diameters, protruding ventrally and causing another bend at the atrioventricular junction. The opening of the atrium narrows to form the **atrioventricular canal**, which enters the ventricle dorsally and from the left. The pericardial cavity expands over the two lateral portions of the atrium, which are then brought closer together, and a constriction is formed between the veins and the atrium (Fig. 7-8).

The proximal portions of the veins become part of a common chamber and are called the right and left **horns of the sinus venosus**. The umbilical and common cardinal veins (from the embryo proper) have joined the vitelline veins on each side just

before they enter the sinus horns (Fig. 7-9,D). The continued bending of the bulboventricular loop eventually folds the bulbus cordis against the atrium on the dorsal and cranial aspect of the heart (Fig. 7-10). The bulbus cordis, which later becomes the conus arteriosus and truncus arteriosus, has remained a relatively narrow tube, and as it presses against the median region of the atrium, the lateral portions bulge out on each side. The resulting two expansions of the atrium are the **primitive right and left atria** (Fig. 7-10). They represent the first division of the heart into its permanent right and left sides.

The tissue between the pericardial cavity and the foregut portal becomes thickened into a mass called the **septum transversum** (Figs. 7-8; 7-10). As the liver cords grow into the septum there is a reorganization of the

**FIG. 7-7.** Human embryo with 8 somites, 2 mm in length. Ventral view of plaster model of heart and pericardial region. Pericardial wall and myocardium removed to expose endocardium. (Redrawn from Davis, 1927.)

**FIG. 7-8.** Human embryo with 11 to 12 somites, 3.09 mm in length. Ventral view of plaster model of heart and pericardial region. Pericardial wall and myocardium removed to expose endocardium. (Redrawn from Davis, 1927.)

veins. The right vein gradually takes over the drainage of blood from the vitelline, umbilical, and posterior cardinal circulations of both sides and is thus the **precursor of the inferior vena cava**. The resultant enlargement of the right horn of the sinus venosus shifts the sinoatrial opening to the right. The right anterior cardinal vein also becomes dominant and shifts the opening somewhat cranialward.

**PARTITIONING OF THE ATRIA.** In the narrow part of the atrium between the two expansions to the right and left of the conus arteriosus, a thin crescent-shaped fold of tissue grows from the dorsocranial wall of the atrium toward the atrioventricular opening. This is known as **septum I** or the **septum primum** (Figs. 7-11,A and B; 7-12). As the septum primum progresses toward the ventricles, two mesenchyme covered endocardial swellings appear in the wall of the atrioventricular canal. These **endocardial cushions** (Fig. 7-11,C and D: AV canal cushions) soon join across the opening, making a division into a right and left atrioventricular opening. The narrowing open space between the advancing septum primum and the endocardial cushions is the **ostium I** or **ostium primum** (Fig. 7-11,B and C). Before the septum primum completely closes the opening between the two atria, which would shut off all flow of blood between them, the substance of the septum primum, near its attachment to the cranial part of the atrial wall, becomes perforated and forms **ostium II** or the **ostium secundum** (Fig. 7-11,C and D).

In the right atrium, a new partition now grows down from the cranial and ventral part of the atrial wall on the right side of septum primum, thus covering the new opening in the first septum. This second crescentic membrane is called the **septum II** or **septum secundum** (Figs. 7-11,D to F; 7-13 to 7-15). Its growth ceases before it is complete, leaving an opening called the **foramen ovale** (Fig. 7-11,E and F). Its crescentic border persists as the **limbus fossae ovalis**, which can still be seen in the adult right atrium. After septum primum has joined with the endocardial cushions, its remaining part becomes thinner and persists as a flap over the foramen ovale below the crescentic edge of septum secundum. At this stage it acts as the **valve of the foramen ovale** (Fig. 7-11,F). After birth, when the foramen ovale is no

**Fig. 7-9.** Four sketches of the ventral view of the developing heart during the fourth week, showing fusion of the heart tubes and bending of the single heart tube. (From Moore, K. L., *The Developing Human*, 2nd Ed., W. B. Saunders Co., 1971.)

**Fig. 7-10.** Human embryo with 20 somites, 3.01 mm in length. Dorsal view of plaster model of heart. (Redrawn from Davis, 1927.)

longer functional, this flap becomes adherent to the limbus and seals the opening. During this development the **pulmonary veins** evaginate from the dorsal wall of the left atrium, but they are of insignificant size because the lungs are still not functioning as aerating organs. The left heart, therefore, receives the bulk of its blood through the foramen ovale rather than from these veins.

**CHANGES IN THE SINUS VENOSUS.** While the interatrial septa are forming, the slit-like opening of the **sinus venosus** into the right atrium is guarded by two valves, the **right and left venous valves** (Figs. 7-12 to 7-15). Above the opening, the two venous valves unite as a single fold, the **septum spurium**, which is a prominent feature at this stage, but is of no significance for the eventual partitioning of the heart (Figs. 7-11; 7-13 to 7-15).

As the right atrium increases in size it absorbs the sinus venosus into its walls (Fig. 7-16,C and D). The upper part of the sinus then becomes the opening for the **superior vena cava**. The inferior part becomes divided by the further growth of the right venous valve into two openings, the **inferior vena cava** and the **coronary sinus** (Fig. 7-16). The left venous valve disappears except for the lower part, which is absorbed into the septum secundum. The upper part of the right venous valve and the septum spurium almost disappear, but are retained in the adult heart as the **crista terminalis** (Fig. 7-11, E and F). The lower part of the right valve persists and is divided into two parts by the growth of a transverse fold, the **sinus septum** (Fig. 7-15). These become the **valve of**

the **inferior vena cava** and the **valve of the coronary sinus**. Of the horns of the sinus venosus, the right becomes much more prominent because it furnishes the inferior and superior venae cavae. The left horn remains small, receiving only the left common cardinal vein. The left anterior cardinal dwindles into the **oblique vein** (Fig. 7-16,F) and the **vestigial fold of Marshall**.<sup>1</sup> The left common cardinal also loses its connection with the body wall and becomes the **coronary sinus**, draining blood only from the substance of the heart (Fig. 7-16).

**DIVISION OF THE VENTRICLES AND PARTITIONING OF THE TRUNCUS ARTERIOSUS.** The primitive ventricle becomes divided by the growth of the **interventricular septum** (Fig. 7-11,A to D). This muscular ridge develops from the most prominent part of the ventricular wall, and its position on the surface of the heart is indicated by a furrow. The dorsal part of the septum grows more rapidly than the ventral and fuses with the dorsal part of the fused endocardial cushions. The opening between the two ventricles remains for some time, but at about the end of the seventh week, it ultimately is closed by the fusion of the **membranous part** of the interventricular septum, derived from the right side of the united endocardial cushions, and the **bulbar ridges**, which appear in the bulbus cordis prior to the partitioning of the truncus arteriosus (Figs. 7-11,D to F; 7-17).

<sup>1</sup>John Marshall (1818-1891): An English anatomist and surgeon (London).

**FIG. 7-11.** Frontal sections of human embryonic heart giving a sequential picture of its progressive partitioning at six different stages of development. Stippled areas indicate endocardial cushion tissue, and the diagonal hatching is the myocardium. In F, the asterisk identifies the membranous part of the interventricular septum. (From Patten, B. M., *Human Embryology*, 3rd Ed. McGraw-Hill, 1968.)

FIG. 7-12. Model of heart of 6.5-mm human embryo, interior of lower half seen from above. (From Tandler, 1912.)

FIG. 7-13. Model of heart of 9-mm human embryo, ventral view of interior of atria. (From Tandler, 1912.)

Closely related to the separation of the ventricles and the closure of the interventricular foramen is the partitioning of the truncus arteriosus into the pulmonary artery and aorta. The conus arteriosus (bulbus cordis) was at first separated from the ventricle by a deep fold, the bulboventricular sulcus. This fold gradually recedes, until the conus and ventricle open freely into each other. This has the effect of allowing the **truncus aortae** to open directly into the ventricle, and it comes to lie in line with the path of the growing interventricular septum. The portion of the ventricular wall that had been the conus remains to the right of the interventricular septum and becomes a part of the adult right ventricle.

The **truncus arteriosus** or **primitive ascending aorta** has at this time developed both its fourth and its sixth, or pulmonary, pairs of arches. The partitioning of the

truncus into the **aorta** and **pulmonary trunk** begins by the growth of two thickenings, called **truncal ridges**, on the interior of the truncus arteriosus at its more cephalic end in the region of the fourth pair of arches. The growth of these ridges toward the bulbus cordis (or conus arteriosus), where they have been called **bulbar ridges**, is such that they follow a spiral course (Fig. 7-18). As it extends away from the heart, the right ridge passes ventrally and then to the left, while the ridge on the left side of the truncus below passes dorsally and to the right as it extends farther from the heart. Their growth inward toward the lumen of the truncus finally results in their fusion, thereby forming a spirally oriented **aorticopulmonary septum** (Fig. 7-18). The truncus arteriosus then becomes divided into the pulmonary trunk and the aorta, but because the aorticopulmonary septum takes the form of a spiral,

**FIG. 7-14.** Interior of the right atrium in the heart of a 25-mm human embryo. (From Licata, 1954.)

**FIG. 7-15.** Interior of the right atrium in the same heart as Figure 7-14 with the right venous valve removed. (From Licata, 1954.)

the two vessels become twisted around each other. Adjacent to the heart, the pulmonary trunk comes to lie anterior and to the right of the aorta, while more distally the pulmonary trunk lies to the left and behind the aorta (Fig. 7-18). The right ventricle becomes connected with the pulmonary arches that go to the lungs, while the left ventricle becomes connected with the fourth arch which forms the aorta.

While the aorticopulmonary septum is partitioning the truncus arteriosus, three small local swellings of endocardial tissue develop in both the aorta and pulmonary trunk at the level of transition between the truncus arteriosus and its ventricular extension, the conus arteriosus. These special swellings become the **semilunar valves**. Two of the valve cusps in each vessel are formed from tissue of the ridges that partition the truncus, and they retain this association of position throughout the subsequent rotation and twisting of the vessels (Fig. 7-19,A and B). The third cusp in each vessel is located opposite the points of fusion of the aorticopulmonary septum and *develops independently* from dorsal and ventral intercalated swellings (Fig. 7-19,C to E).

**BEGINNING OF CONTRACTION.** The first contractions of the heart have not been observed in human embryos, but it can be assumed that they follow the same sequence as in other mammals. In a rat embryo with three somites (Fig. 7-3), two lateral heart tubes are recognizable. On the ventricular side of a slight constriction that marks the future atrioventricular junction, a small group of cells in the splanchnic mesoderm begins contracting with a regular rhythm. In a rat embryo, the left lateral heart initiates the contraction at a rate of 20 to 30 per minute. A few hours later, the right heart commences with a slower rate and a regular rhythm independent of the left side. As the contraction involves the median portion of the ventricle, the rate increases gradually, the left side acting as pacemaker. By the time the rate has reached 90 per minute, a small part of the atrium adjacent to the atrioventricular junction has begun contraction and acts as the pacemaker, but with a distinct interval between the atrial and ventricular contraction (Goss, 1940, 1942). It is reasonable to conclude from these studies on subhuman mammals that *the developing human heart begins contracting at the end of the*

third prenatal week or the beginning of the fourth week, i.e., on the twenty-first or twenty-second day.

**BEGINNING OF CIRCULATION.** The primitive heart, as it enlarges and differentiates, continues to contract after the three-somite stage, but in embryonic rats it is ineffective for circulation until the embryo has eight or nine somites (Fig. 7-7). By that time the atrium is well established, the ventricle is an effective muscular pump, the cells in the blood islands of the yolk sac have acquired hemoglobin, and a continuous lumen has been established through the aortae, the umbilical and omphalomesenteric arteries, the yolk sac, and the placental capillaries, and back through the corresponding veins to the heart (Goss, 1942).

The development of the arteries and veins is described at the beginning of the corresponding chapters.

## Peculiarities in the Vascular System of the Fetus

**FETAL HEART.** The chief peculiarities of the fetal heart are the direct communication between the atria and the foramen ovale, and the large size of the valve of the inferior vena cava. Among other peculiarities the following may be noted: (1) In early fetal life

the heart lies immediately below the mandibular arch and is relatively large in size. As development proceeds, it is gradually drawn within the thorax, but at first it lies in the midline; toward the end of pregnancy it gradually becomes oriented obliquely toward the left. (2) For a time the atrial portion exceeds the ventricular in size, and the walls of the ventricles are of equal thickness; toward the end of fetal life the ventricular portion becomes the larger and the wall of the left ventricle exceeds that of the right in thickness. (3) The size of the fetal heart is large in relation to the size of the rest of the body, the proportion at the second fetal month being 1 to 50, and at birth, 1 to 120, while in the adult the average is about 1 to 160.

The **foramen ovale**, situated at the lower part of the atrial septum, forms a free communication between the atria until the end of fetal life. A septum (**septum secundum**) grows down from the upper wall of the atrium to the right of **septum primum**, in which the foramen ovale is situated. Shortly after birth, the two septa fuse, and the foramen ovale is obliterated.

The **valve of the inferior vena cava** serves to direct the blood from that vessel through the foramen ovale into the left atrium.

**FETAL ARTERIAL SYSTEM.** The principal peculiarities of the arterial system of the fetus are the communication between the

pulmonary artery and the aorta by means of the ductus arteriosus, and the continuation of the internal iliac arteries as the umbilical arteries to the placenta.

The **ductus arteriosus** is a short tube, about 1.25 cm in length at birth, and 4.4 mm in diameter. In the early condition it forms the continuation of the pulmonary artery and opens into the aorta just beyond the origin of the left subclavian artery (Fig. 7-20). Most of the blood that leaves the right ventricle is conducted by way of the ductus arteriosus into the aorta. When the branches of the pulmonary artery become larger than the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery.

The **internal iliac arteries** course along the sides of the bladder and then turn upward on the inner aspect of the anterior abdominal wall to reach the umbilicus. At the umbilicus they pass out of the abdomen and are continued as the **umbilical arteries** in the umbilical cord to the placenta (Fig. 7-20). They convey blood from the fetal arterial system to the placenta.

**FETAL VENOUS SYSTEM.** The peculiarities in the venous system of the fetus are the communications established between the placenta and the liver and portal vein, through the **umbilical vein**, and between the umbilical vein and the inferior vena cava through the **ductus venosus** (Fig. 7-20).

#### FETAL CIRCULATION

In early fetuses blood is returned from the placenta to the umbilical orifice by a single umbilical vein, which then divides into right and left umbilical veins. The *right umbilical vein* becomes atrophic early and then completely disappears, leaving the *left umbilical vein*, which remains functional until birth (Fig. 7-20). This vein enters the abdomen at the umbilicus and passes upward along the free margin of the falciform ligament of the liver to the caudal surface of that organ, where it gives off several branches, a large one to the left lobe and others to the quadrate lobe and caudate lobe. At the **porta hepatis** it divides into two branches, of which the larger is joined by the portal vein and enters the right lobe of the liver and the smaller is continued cranially as the **ductus venosus** to join the inferior vena cava (Fig. 7-20). The blood that traverses the umbilical vein, therefore, passes to the inferior vena

cava in three different ways: (1) a considerable quantity circulates through the liver with the portal venous blood before entering the inferior vena cava by the hepatic veins; (2) some blood enters the liver directly, and is carried to the inferior vena cava by the hepatic veins; and (3) the remainder passes directly into the inferior vena cava through the ductus venosus.

In the inferior vena cava, the blood carried by the ductus venosus and hepatic veins becomes mixed with that returning from the lower extremities and abdominal wall. Entering the right atrium, and guided by the valve of the inferior vena cava, it passes through the foramen ovale into the left atrium, where it mixes with a small quantity of blood returned from the lungs by the pulmonary veins. From the left atrium it passes into the left ventricle and then into the aorta, through which it is distributed almost entirely to the heart, head, and upper extremities; a small quantity is probably also carried into the descending aorta. From the head and upper limbs the blood is returned by the superior vena cava to the right atrium, where it mixes with a small portion of the blood from the inferior vena cava. From the right atrium it passes into the right ventricle, and thence into the pulmonary artery. Because the lungs of the fetus are inactive, only a *small quantity* of the blood in the pulmonary artery is distributed to them by the right and left pulmonary arteries. The blood that does go to the lungs is returned by the pulmonary veins to the left atrium. By far the *larger quantity* of blood in the pulmonary artery passes through the ductus arteriosus into the aorta, where it mixes with a small quantity of the blood transmitted by the left ventricle into the aorta. By means of this vessel, it is in part distributed to the lower limbs and the viscera of the abdomen and pelvis, but the greater amount is conveyed by the umbilical arteries to the placenta (Fig. 7-20).

From the preceding account of the circulation of the blood in the fetus, which has been based on solid research evidence, the following facts can be documented: (1) The placenta serves the purposes of nutrition and excretion, receiving impure blood that is low in oxygen from the fetus and returning it oxygenated and charged with additional nutritive material. (2) About half of the blood of the umbilical vein traverses the

**FIG. 7-20.** A simplified schema of the fetal circulation. Colors indicate degree of oxygen saturation of the blood. Brightest red is highest oxygen saturation, while deepest blue is the lowest oxygen saturation.

liver before entering the inferior vena cava; this accounts for the large size of the liver, especially at an early period of fetal life. The remainder of the blood in the umbilical vein bypasses the liver and enters the inferior vena cava through the ductus venosus. (3) The right atrium receives blood from two sources, the inferior vena cava and the superior vena cava. At an early period of fetal life, it is quite probable that these two streams remain nearly distinct. Most of the blood flowing in the inferior vena cava is guided by the valve of this vessel directly through the foramen ovale and into the left atrium, but a small amount does seem to mix with blood returning to the right atrium from the head and upper limbs by way of the superior vena cava. It is from these latter sources that blood enters the right ventricle and exits from the pulmonary artery. Because the pressure in the right atrium exceeds that in the left atrium (which receives only a small amount of blood from the lungs by means of the pulmonary veins), the valve of the foramen ovale (septum primum) opens to the left, allowing blood from the inferior vena cava to flow from the right atrium to the left atrium. (4) The highly oxygenated (about 80% O<sub>2</sub> saturated) blood carried from the placenta to the fetus by the umbilical vein, mixed with the blood from the portal vein and inferior vena cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head for the developing brain and to the upper limbs. (5) The blood contained in the descending aorta, derived chiefly from that which has already circulated through the head and upper limbs, together with a small quantity from the left ventricle, is distributed to the abdomen and lower limbs.

#### CHANGES IN THE VASCULAR SYSTEM AT BIRTH

When breathing commences in the newborn child, an increased amount of blood from the pulmonary artery passes through the lungs, and the placental circulation is eliminated by ligation of the umbilical cord. The **foramen ovale** gradually decreases in size during the first month, but a small opening frequently persists until the latter part of

the first year. The valve of the foramen ovale adheres to the margin of the foramen for the greater part of its circumference, and thereby the septum primum begins to fuse with septum secundum. A slit-like opening, however, may persist between the two atria. Unless this opening is large, it is of no functional significance.

The **ductus arteriosus** begins to contract immediately after respiration is established, and its lumen gradually becomes obliterated. It ultimately becomes an impervious cord, the **ligamentum arteriosum**, which connects the left pulmonary artery to the arch of the aorta (Figs. 7-21; 7-26).

The portions of the **internal iliac arteries** that extend from the sides of the bladder to the umbilicus become obliterated between the second and fifth days after birth, and persist as fibrous cords covered with peritoneum, the **medial umbilical ligaments**. These form ridges on the inner surface of the anterior abdominal wall.

The **umbilical vein** and **ductus venosus** no longer receive blood after the umbilical cord has been severed. The umbilical vein becomes the **ligamentum teres**, while the ductus venosus becomes the **ligamentum venosus** of the liver. The hepatic half of the ductus venosus may remain open, receive tributaries from the liver, and thus function as a hepatic vein in the adult.

## The Pericardium

Except for its continuity with the roots of the great vessels, the heart is unattached to other organs in the thoracic cavity. It is maintained in its proper position by these vessels and by an enclosing fibroserous sac, the **pericardium**, which allows the living heart an appropriate freedom of movement required for its contraction cycles (Figs. 7-21; 7-24). The pericardium consists of two quite different components, the membranous **serous pericardium** and the thicker **fibrous pericardium**.

**SEROUS PERICARDIUM.** The serous pericardium is composed of a single layer of mesothelial cells. It lines the inner surface of the fibrous pericardium and is continuous at the roots of the great vessels with the epicardium that forms the outermost layer of the heart wall itself. Its characteristics are such that it provides the interfacing pericar-

**Fig. 7-21.** Anterior view of the dorsal aspect of the pericardial sac with the heart removed. Observe especially the oblique and transverse pericardial sinuses and the eight cut blood vessels that enter or leave the heart. Pulmonary veins and aorta colored red to indicate oxygenated blood; superior and inferior vena cavae and pulmonary artery colored blue to indicate blood with low oxygen levels. (After Sobotta.)

dial sac and heart with smooth and glistening surfaces that are completely free and movable. The serous layer of the heart itself may be considered the **visceral pericardium**. It covers the atria and ventricles and extends beyond them along the great vessels for 2 or 3 cm (Fig. 7-21). The serous layer lining the fibrous sac may be considered the **parietal pericardium**. Along the roots of the great vessels this continuous serous membrane folds upon itself, and the point at which the visceral layer becomes the parietal layer is called the **reflection of the pericardium**.

**PERICARDIAL CAVITY.** Under normal conditions the two serous membranes are closely apposed, being separated only by enough serous or watery fluid to moisten their surfaces. This allows the heart to move easily during its contraction in systole and its re-

laxation in diastole. Because the two surfaces are not fused, there is a potential space between them called the **pericardial cavity**, not unlike the pleural cavity. After injury or due to disease, fluid may exude into the cavity, causing a wide separation between the epicardium and the fibroserous pericardium.

The extension of the epicardium on the great vessels is in the form of two tubular prolongations. One encloses the aorta and pulmonary trunk and is called the **arterial mesocardium**. The other encloses the superior and inferior venae cavae and the four pulmonary veins and is called the **venous mesocardium**. The reflection of the venous mesocardium forms a U-shaped cul-de-sac in the dorsal wall of the pericardial cavity called the **oblique pericardial sinus** (Fig. 7-21). Between the arterial mesocardium and

the venous mesocardium is a serous-lined passage named the **transverse pericardial sinus** (Fig. 7-21).

**FIBROUS PERICARDIUM.** The fibrous pericardium forms a cone-shaped sac, the neck of which is closed by its attachment to the great vessels just beyond the reflection of the serous pericardium (Fig. 7-21). It is a tough, dense membrane, much thicker than the parietal pleura. Its outer surface is adherent in varying degrees to all the structures surrounding it. It is attached *anteriorly* to the manubrium of the sternum by a fibrous condensation, the **superior pericardiosternal ligament**, and to the xiphoid process by the **inferior pericardiosternal ligament**. The fibrous tissue intervening *posteriorly* between the pericardial sac and the vertebral column is the pericardiovertebral ligament. The sac is securely attached *inferiorly* to the central tendon and muscular part of the left side of the dome of the diaphragm. A thickening of this fibrous attachment in the region of the inferior vena cava has been called the **pericardiophrenic ligament**.

**LIGAMENT OF THE LEFT VENA CAVA.** This small fibrous strand is covered by a triangular fold of serous pericardium, and it stretches from the left pulmonary artery to the atrial wall or the subjacent pulmonary vein. It is formed by the remnant of the left common cardinal vein (or left duct of Cuvier) which becomes obliterated during fetal life. If well developed, it may remain as a fibrous band stretching from the highest left intercostal vein to a small vein draining into the coronary sinus, the **oblique vein of the left atrium** (vein of Marshall).

**RELATIONS OF THE PERICARDIAL SURFACES.** Laterally, the surfaces of the pericardial sac are apposed to the mediastinal parietal pleura. The pericardium and the mediastinal pleura are adherent but not fused, and the phrenic nerve with its accompanying blood vessels is held between them as it descends in the thorax. Because of the rounded contour of the heart, the pleural cavity partly encircles the pericardial sac, extending *anteriorly* between it and the chest wall except for a small triangular area on the left side (Figs. 3-14; 3-17). This area corresponds to the caudal portion of the body of the sternum and the medial ends of the left fourth and fifth costal cartilages. As mentioned above, in percussion of the chest for physical diagnosis, the triangle is called the area

of superficial cardiac dullness because no lung is present to give it resonance. This site is also important clinically as the area through which a needle can be introduced into the pericardial cavity for removal of excess fluid, without traversing the pleural cavity or lungs. More superiorly, the anterior surface may be in contact with the thymus in children. *Posteriorly*, the pericardial sac is in relation to the bronchi, esophagus, and descending thoracic aorta. *Inferiorly*, the pericardium is attached to the dome of the diaphragm.

## General Features of the Heart

The **heart** is a hollow muscular organ shaped like a blunt cone and comparable in size to a human fist. It rests on the diaphragm between the lower part of the two lungs (Figs. 7-22; 7-23). It is enclosed in a fibroserous sac, the pericardium, and occupies a topographical compartment of the thorax called the **middle mediastinum** (Fig. 7-24). Its position relative to the chest wall is described in Chapter 3 and shown diagrammatically in Figure 7-22, and the position and extent of the cardiac shadow in a roentgenogram are shown in Figure 7-23. The heart is partially covered anteriorly by the mediastinal borders of the lungs, although a triangular region, which can be outlined by percussion, is not covered with lung tissue and is called the **area of superficial cardiac dullness**. The heart lies deep to the sternum and adjoining parts of the third to sixth costal cartilages. Its **apex** is directed downward, anteriorly, and to the left. Projecting farther into the left half of the thorax than the right, two-thirds of the heart lies to the left and one-third lies to the right of the median plane (Fig. 7-24).

**SIZE.** The average adult heart measures about 12 cm in length, 8 to 9 cm transversely at the broadest part, and 6 cm anteroposteriorly in thickness. Its weight, in the male, varies from 280 to 340 grams; in the female, from 230 to 280 grams. The heart frequently continues to increase in weight and size until an advanced period of life. This increase is more marked in men than in women, and in many instances is pathological.

**HEART WALL.** The wall of the heart is composed of three layers: the outermost is the

**Fig. 7-22.** The heart and cardiac valves projected on the anterior chest wall, showing their relation to the ribs, sternum, and diaphragm. P = pulmonary valve; A = aortic valve; T = tricuspid valve; M = mitral valve. (From Eycleshymer and Jones.)

**epicardium**, deep to this is the **myocardium**, and the innermost is the **endocardium**.

The surface layer, or **epicardium**, is a serous membrane that is continuous with the inner lining of the fibrous pericardium and reflects over the heart wall at the roots of the great vessels, and can, therefore, be considered the **visceral pericardium**. It consists of a single sheet of squamous mesothelial cells resting on a lamina propria of delicate connective tissue. Between the epicardium and the myocardium is a layer of heavier fibroelastic connective tissue, which is interspersed with fatty tissue that fills in the crevices and sulci to give the heart a smooth, rounded contour. The larger blood vessels and the nerves are also found in this connective tissue. The dark reddish color of the myocardium is visible through the epicar-

dium except where fat has accumulated. The amount of fat varies greatly, but is seldom absent except in emaciated individuals. It may almost completely obscure the myocardium in the very obese.

The **myocardium** is composed of layers and bundles of cardiac muscle with a minimum of other tissue except for the blood vessels. Its detailed structure is described in a later section.

The **endocardium** is the inner lining of the heart. Its surface layer is composed of squamous endothelial cells, and it is continuous with the endothelial lining of the contiguous blood vessels. The connective tissue between this endothelial lining and the myocardium is quite thin and transparent over the muscular walls of the ventricles, but is thickened in the atria and at the attachments

of the valves. It contains small blood vessels, parts of the specialized conduction system, and a few bundles of smooth muscle.

## External Features of the Heart
